Executive Summary

This report describes the sampling design, sample selection, estimation procedures, and the missing data compensation procedures used for the *1996 Status of the Armed Forces Surveys (SAFS) Form D—Equal Opportunity*; this survey is referred to as the *1996 Equal Opportunity Survey (EOS)*. This report provides statistical background information for the datasets and reports of the survey results.

The population of inferential interest for the *EOS* consisted of the worldwide distribution of active-duty Army, Navy, Marine Corps, Air Force, and Coast Guard members (including Reservists on active duty) below the rank of admiral or general, with at least six months of active-duty service. Members of the National Guard and Reserves were in the population for the survey if they were in active-duty assignments (e.g., Active Guard and Reserve (AGR) and Navy Training and Administration of Reserve (TAR)) for at least 179 days.

The main purposes of the survey were to provide survey data on types, frequency, and effects of racial/ethnic harassment and discrimination experienced by active-duty military; context, location, and circumstances under which the experiences occur; racial climate within the larger organizational climate; characteristics of the complaint process; and effectiveness of current policies/training designed to prevent, reduce, and eliminate racial/ethnic harassment and discrimination. The questionnaire for *EOS* was developed specifically for this survey effort. Data collection for the surveys was by mail. Survey development, administration, and datasets were reported by Edwards, Elig, and Riemer (1997).

Sampling Design

The initial sample for the *EOS* consisted of a stratified random sample of 76,754 individuals, of whom 73,496 were ultimately determined to be eligible members of the target population. Stratum definitions for the survey consisted of Service (Army, Navy, Marine Corps, Air Force, Coast Guard, and AGR/TARs), location (United States versus outside the United States), paygrade group (E1 through E3, E4, E5 through E6, E7 through E9, and WO1 through O6), and race/ethnicity (non-Hispanic White, non-Hispanic Black, Hispanic, Native American & Alaska Native, Asian & Pacific Islander, and Other). In addition, there was an unknown stratum containing individuals for whom one or more of the stratum variable values were missing.

The total sample size and allocation for *EOS* was determined to satisfy precision constraints imposed on estimates of prevalence rates in key reporting domains. The prevalence rate can be thought of as any proportion to be estimated from a survey, such as the proportion of persons who report incidents of racial/ethnic harassment or discrimination. The sampling design considered reporting domains (subgroups for which results would have to be reported with known accuracy) defined by different combinations of Service, racial/ethnic group membership (Hispanic, non-Hispanic Black, non-Hispanic White, Asian & Pacific Islander, and Native American & Alaska Native), paygrade, location (US, Europe, Asia/Pacific Islands), and density in duty occupations of blacks, Hispanics, and total minorities.

A formal mathematical procedure was used to determine the sample size and allocation. The procedure involved developing equations to describe the variance of the sample estimates and the variable survey costs, then simultaneously solving the equations subject to the (inequality) precision requirements. The solution obtained was unique and was that allocation of the sample that jointly satisfied the precision requirements for the least cost.

The sample of individuals was selected with equal conditional probabilities given the stratum allocations. However, because the stratum allocations were not proportional to the stratum sizes, sample individuals were not selected with equal overall probabilities.

Missing Data Compensation Procedures

When the survey fielding closed in February 1997, response status was determined for 43,113 individuals, of whom 3,258 were determined to be ineligible and 39,855 were determined to be respondents who had returned usable surveys. After making adjustments for eligibility and differential sampling rates across the various subgroups, the response rate was 52.7%.

Weights were generated so that estimates from the survey would represent the population of interest. The weights reflect (a) the probability of selection for that member, (b) a nonresponse adjustment factor to minimize bias arising from differential response rates among demographic subgroups of the population, and (c) a poststratification factor for September 1996, the month the survey form was first distributed.

The procedure used to adjust for nonresponse for *EOS* was a combination of a Chi-squared Automatic Interaction Detector (CHAID) analysis to determine variables related to nonresponse, and logistic modeling of response propensity. A logistic regression model was developed where the independent variable was an indicator variable which was "1" if the sampled person was a respondent and was "0" otherwise. Dependent variables were those selected by CHAID as being related to the likelihood of response and also some additional variables important for analytic considerations. This regression model was used to obtain predicted values of the response probability with the same values of the independent variables. The inverse of this estimated response rate was used to adjust the sampling weight of the respondents. Independent variables for the model included those used to define the sampling strata (i.e., Service, component, race/ethnicity, paygrade, and location). Other variables used were education, marital status, gender, and minority density in the Service members' occupations groups. The response propensity modeling procedure is similar to the weighting class adjustment procedure that is often used to adjust sampling weights for nonresponse; however, the modeling procedure allows for the inclusion of a greater number of variables.

THE 1996 ARMED FORCES EQUAL OPPORTUNITY SURVEY: STATISTICAL METHODOLOGY REPORT

Introduction

This report describes the statistical methodology used for sampling and weighting for the *1996 Status of the Armed Forces Surveys (SAFS) Form D—Equal Opportunity*. The survey is referred to as the *1996 Equal Opportunity Survey (EOS)*. Separate sections of the report describe the sampling design and selection, missing data compensation procedures, and survey performance rates. Appendices to this report provide supplementary tables, give detailed statistical derivations and estimation procedures, and describe the contents of the data files that document the weighting procedures and analyses. A glossary (see Appendix G) is provided to help readers understand technical terms used in this report; words and phrases in italics appear in the glossary.

Remaining portions of this introductory section provide an overview of the survey and introduce key features of the statistical methodology for the survey.

Survey Overview

Survey development and administration are described by Edwards, Elig, and Riemer (1997). The main purposes of the survey were to provide survey data on types, frequency, and effects of racial/ethnic harassment and discrimination experienced by active-duty military; context, location, and circumstances under which the experiences occur; racial climate within the larger organizational climate; characteristics of the complaint process; and effectiveness of current policies/training designed to prevent, reduce, and eliminate racial/ethnic harassment and discrimination. The questionnaire for *EOS* was developed specifically for this survey effort.

Data collection for the survey was by mail. Individuals in the sample initially received an introductory letter explaining the survey and soliciting cooperation. The letter was followed by a package containing the questionnaire and a letter requesting that the survey be completed. The package was followed by another letter thanking the individual if the questionnaire had been returned, and asking for its return if it had not been. After specified times had elapsed, a second and a third package containing the questionnaire and letters stressing the importance of the survey were mailed to nonrespondents to the previous mailings.

Summary Description of the Sampling Design

The population of inferential interest for the *EOS* consisted of the worldwide distribution of active-duty Army, Navy, Marine Corps, Air Force, and Coast Guard members (including Reservists on active duty) below the rank of admiral or general, with at least six months of active-duty service. Members of the National Guard and Reserves were in the population for the survey if they were in active-duty assignments (e.g., Active Guard and Reserve (AGR) and Navy Training and Administration of Reserve (TAR)) for at least 179 days.

The initial sample for the *EOS* consisted of a stratified random sample of 76,754 individuals, of whom 73,496 were ultimately determined to be eligible members of the target population. Source information for constructing the sampling frame was taken from the Defense Manpower Data Center's (DMDC's) April 1996 Active Duty Master File (ADMF) and the April 1996 Reserve Components Common Personnel Data System (RCCPDS). The ADMF and RCCPDS provided the information for constructing *strata* and for defining the key reporting *domains* that provided the basis for determining the sample size and allocation.

Stratum definitions for the survey consisted of:

- Service: Army, Navy, Marine Corps, Air Force, Coast Guard, and AGR/TARs.
- Location: United States (US) vs. outside the United States (Overseas). For this survey, US included all 50 States and the District of Columbia, whereas Overseas included all other countries, United States Territories, and Naval personnel aboard ships afloat in ports outside the US and afloat at sea.
- Paygrade: E1 through E3, E4, E5 through E6, E7 through E9, and WO1 through O6.
- Race/ethnicity: non-Hispanic White, non-Hispanic Black, Hispanic, Native American & Alaska Native, Asian & Pacific Islander, and Other.
- An unknown stratum: All individuals for whom one or more of the above stratum variable values were missing.

The total *sample size* and allocation for *EOS* was determined by satisfying precision constraints imposed on estimates of prevalence rates in key reporting domains. The prevalence rate can be thought of as any proportion to be estimated from a survey, such as the proportion of persons who report incidents of racial/ethnic harassment or discrimination. The sampling design considered reporting domains (subgroups for which results would have to be reported with known accuracy) defined by different combinations of Service, racial/ethnic group membership (Hispanic, non-Hispanic Black, non-Hispanic White, Asian & Pacific Islander, and Native American & Alaska Native), paygrade, location (US, Europe, Asia/Pacific Islands), and density in duty occupations of blacks, Hispanics, and total minorities. For 172 reporting domains, maximum *confidence interval half-widths* of 0.012 to 0.08 were specified for a prevalence rate of 0.5.

A formal mathematical procedure based on Karush-Kuhn-Tucker theory was used to determine the sample size and allocation. The procedure involved developing equations to describe the variance of the sample estimates and the variable survey costs, then simultaneously solving the equations subject to the (inequality) precision requirements. The obtained solution was unique and was the sample allocation that jointly satisfied the precision requirements for the least cost.

The sample of individuals was selected with equal conditional probabilities given the stratum allocations. Because the stratum allocations were not proportional to the stratum sizes, sample individuals were not selected with equal overall probabilities.

The sample frame included only those members who were on active duty in April 1996, with eligibility conditional on also being on active-duty in June and September 1996. Sampled individuals were compared against DMDC's Defense Enrollment Eligibility Reporting System (DEERS) end-of-month Extract file for June 1996 and September 1996 to obtain updated information on survey eligibility.

Summary Description of the Missing Data Compensation Procedures

When the survey fielding closed in February 1997, response status was determined for 43,113 individuals, of whom 3,258 were determined to be ineligible and 39,855 were determined to be respondents who had returned usable surveys. After making adjustments for eligibility and differential sampling rates across the various subgroups, the response rate was 52.7%.

Weights were generated so that estimates from the survey would represent the population of interest. The weights reflect (a) the probability of selection for that member, (b) a nonresponse adjustment factor to minimize bias arising from differential response rates among demographic subgroups of the population, and (c) a poststratification factor for September 1996, the month the survey form was first distributed.

The procedure used to generate the nonresponse adjustment factor was logistic modeling of unit response propensity. A logistic regression model was developed where the independent variable was an indicator variable which was one if the sampled person was a respondent and was zero otherwise. Dependent variables were related to the likelihood of response and to analytic considerations and were chosen using CHAID (Magidson, 1993). This regression model was used to obtain predicted values of the response probability with the same values of the independent variables. The inverse of this estimated response rate was used to adjust the sampling weight of the respondents. Potential independent variables for the model included those used to define the sampling strata (i.e., Service, component, race/ethnicity, paygrade, and location) and other variables, such as education, gender, marital status, and percent minority in the sampled members' occupation groups. The response propensity modeling procedure is similar to the weighting class adjustment procedure often used to adjust sampling weights for nonresponse.

Poststratification was used to force the response-adjusted weights to sum to the counts of active duty personnel as of September 1996 to create the final analysis weight.

Sampling Design

This section of the report describes:

- the inferential requirements for the survey including the inferential population definition, key reporting domains or subpopulations defined within the overall population, and the precision requirements imposed on sample estimates of parameters describing the key domains;
- the construction and stratification of the sampling frame;
- the procedure followed to determine the sample size and allocation; and
- selection of the sample.

A distinction is made between *sample size* and *number of observations*. Sample size refers to the number of persons selected into the sample. Sample sizes are determined to provide a specified number of observations given the anticipated eligibility and response rates for the survey. The sample is the group of persons to whom a questionnaire is to be administered. Number of observations, on the other hand, refers to the number of persons eligible to participate in the survey who returned a questionnaire with key items completed.

A distinction is also made between *strata* and *domains*. Stratification is a feature of the sampling design, used to control the distribution of the sample. Strata partition the inferential population in the mathematical sense. That is, each individual in the population is classified into only one stratum, and the set of all strata includes the entire population. By contrast, a single individual can simultaneously belong to one or more domains. The set of domains, as a consequence, does not partition the population and is itself arbitrary, depending largely on the interests of the investigators analyzing the data. *Key domains* are identified in advance of the survey to provide the basis for determining the sample size and allocation.

Overview of the Sampling Design

A stratified random sampling design was used for *EOS*. Source information for constructing the sampling frame and identifying key domains consisted of a computer accessible file totaling 1,573,663 records. The file contained information extracted from two DMDC person-level files: the April 1996 ADMF and the April RCCPDS.

Within each stratum, persons were sampled with equal conditional probabilities, and without replacement. Stratum level sample sizes were determined by variance constraints imposed on key parameter estimates of the proportion of persons belonging to specified domains. Parameter estimates used were percentages who would report having experienced one or more of the behaviors defined in the survey as racial/ethnic harassment or discrimination. The total sample size for the *EOS* was 76,754.

Inferential Requirements

The inferential requirements for a survey are described in terms of

- a fully operational definition of the population of inferential interest (i.e., the target population),
- key parameters used in developing the design, and
- the precision requirements for the survey, stated in terms of the maximum values of the variances to be associated with the sample estimates of the key parameters.

The population definition identifies all individuals for whom conclusions are to be reached or about whom inferences are to be made based on the survey data. The definition generally includes a spatial and a temporal component.

Key parameters used as the basis for the design may be defined in terms of characteristics of the overall population, characteristics of subpopulations of special interest (key domains), tests of hypotheses (including standardized comparisons), and the relations that exist at population levels among specified observation variables. For this survey, the key parameters were prevalence rates, defined as the proportion of persons belonging to specified domains who would report having experienced one or more of the behaviors defined in the survey as racial/ethnic harassment or discrimination. The prevalence rates used for design purposes were chosen by the investigators based on policy and programmatic considerations and on the resources available for undertaking the surveys.

The precision requirements for the *EOS* were defined in terms of the maximum *confidence interval half-widths* to be associated with a priori estimates of the specified prevalence rates in specified key domains.

Population Definition

The population of inferential interest for the *EOS* consisted of all military personnel below flag rank in the Army, Navy, Marine Corps, Air Force, and Coast Guard, including AGR/TARS program members of the National Guard and Reserves.

The survey was worldwide in scope and included active-duty individuals below flag rank when selected into the sample: (a) who were members of a Service in the April 1996 ADMF or Reserve Components individuals who were members of a program (e.g., AGR/TARS) on active-duty in the April 1996 RCCPDS, and (b) who were also in active-duty status in June and September 1996. If not in active-duty in June or September 1996, sampled persons were flagged as ineligible. The eligible population was approximately limited to members with at least six months service when surveyed. After the sample was selected, eligibility of sampled members was checked by comparing to the DEERS end-of-month Extract file for June 1996 and September 1996.

Key Reporting Domains

The factors used to define the key reporting domains are listed in Table 1. An initial set of candidate domains was generated by considering various combinations of, and crosses among, the factors listed in the table. Because the domain sizes interact with the precision requirements imposed on the domain prevalence estimates to determine the overall sample size and allocation, several iterations were required to develop domain definitions consistent with the objectives of the survey and the resources available to carry out the survey.

The factors listed in Table 1 are generally self-explanatory. The Black density, Hispanic density, and minority density groupings were constructed using the distribution of Blacks, Hispanics, or minorities in occupational specialties and are described in more detail in the Missing Data Compensation section of this report and by Edwards et al. (1977). Precision constraints were not set for either these density groupings or the individual ethnic groups in the final sample allocation.

Precision Requirements

In general, precision requirements are specified as the maximum values of the sampling variances to be associated with parameters estimates for key domains. Both the values of the parameters and the values of the variances are needed to complete the specification. The sampling variances are functions of the sample size, the distribution of the sample, population variances, and design constants. Because information about the values of population variances is typically lacking in advance of the survey, a convenient way to specify the precision requirements is in terms of the sampling variances to be associated with estimates of domain proportions (i.e., estimates of the proportion of individuals belonging to specified domains who possess characteristics or attributes of particular interest). By using this convention, the (binomial) population variances are coincidentally specified with the specification of the proportions.

For this survey, the parameters used for specifying the precision requirements were the proportions of individuals who would report having experienced one or more of the behaviors defining racial/ethnic harassment or discrimination. These behaviors are defined by Questions 29, 30, and 31 on the *EOS* questionnaire.

The parameter values used for the design are the prevalences listed in Appendix B in Table B-1. As is the case with the domain sizes, the values of the prevalence rates chosen to provide the basis for the precision requirements influence the size and cost of the survey.

The maximum values of the variances to be associated with the sample estimates of the prevalence rates were, for this survey, specified in the form of confidence interval half-widths. Both the cost implications and the objectives of the survey were considered in specifying these values. On the one hand, the intervals had to be small enough to provide an informative study. On the other hand, they could not be so restrictive as to be unaffordable. Table B-1 lists the half-width intervals together with the domain definitions, domain sizes, and prevalence rates.

Table 1.
Factors Defining Key Reporting Domains

Factors	Levels
Black Density	High Density Low Density

Race/Ethnicity 3	non-Hispanic White non-Hispanic Black Hispanic Asian, Pacific Islander, Native American, Alaska Native, & Other
Region 1	US Europe Asia & Pacific Islands Other
Region 2	US Overseas
Service/Component	Army Navy Marine Corps Air Force Coast Guard AGR/TARs

Sampling Frame Construction and Stratification

A distinction is made between *dimensions of stratification* and *levels of stratification*. The dimensions are the variables used to stratify the sample/population whereas the levels are the values present within a dimension. Table 2 presents the stratification dimensions and levels.

Table 2.
Source Information Used for Stratification

Dimension of Stratification	Levels of Stratification
Service	Army Navy Marine Corps Air Force Coast Guard
Component	Active AGR from a Reserve component (e.g., TAR) AGR from a National Guard component
Location	US Overseas
Paygrade group	E1 to E3 E4, E0 E5 to E6 E7 to E9 Officers: WO1 to WO5, O1 to O6, W0, O0
Race/ethnicity	non-Hispanic White non-Hispanic Black Hispanic American Indian/Alaska Native Asian/Pacific Islander Other

Preliminary Stratification

As a starting point, paygrades were combined to form the following groups: four levels of enlisted personnel (E1 to E3, E4, E5 to E6, and E7 to E9), and an officer group consisting of all warrant officers (W01-W05) and commissioned officers (O1 to O6). Using these groupings in place of individual paygrades, a candidate set of strata was constructed by crossing all of the levels in Table 2, yielding 900 potential strata. While some combinations of Service and component do not exist, the crossing of these two dimensions resulted in a large number of strata that do not contribute to greater precision for key reporting domains. A decision was made to reduce the number of potential strata to 360 by classifying members of any Reserve or Guard component into an AGR/TAR level in a redefined Service dimension of stratification.

The next step was to consider the minimum stratum size consistent with a total sample size of 60,000. The figure of 60,000 people was the originally targeted sample size for *EOS*, although this number was later increased. If unbiased variances for linear statistics are to be a design requirement, then a minimum of two observations is needed in any stratum. However, if a stratum is too small, then insisting on at least two observations from that stratum introduces an unequal weighting effect that acts to increase variances for no reason other than the stratum is

simply too small. Even if only a few strata are too small, the cumulative unequal weighting effects can compromise any variance advantage associated with having stratified in the first place.

This consideration lead to defining "too small" in terms of a proportional allocation of the total sample. A proportional allocation of the sample cannot, by definition, introduce unequal weighting effects. Given a proportional allocation and a minimum requirement of two observations per stratum, the minimum stratum size was computed as,

$$\min\{N_h\} = \frac{2N}{n},$$

where,

N_h = the size of the h - th stratum,

N = the size of the population, and,

n = the total size of the sample.

For $N = 1,573,663$ and $n = 60,000$, a minimum stratum size of $\min\{N_h\} = 53$ was indicated.

Next, the proportion of the total strata defined by all possible crosses that were below the minimum size of 53 was computed for each of the initial stratification variables. The decisions about which strata to collapse were based on identifying the candidate stratification dimensions with consistent patterns of deficient strata and on a consideration of the relative importance of specific candidate stratification dimensions to the surveys. Thus, an initial decision to collapse Native Americans¹ with other races was reversed because Native Americans are an important analytic group, despite the consistent dearth of Native Americans in most of the strata defined by crossing this stratification level with levels from other stratification variables. On the other hand, the consistent pattern of too few AGR/TARS and Coast Guard personnel overseas resulted in their being collapsed. Specific levels that were collapsed were:

- US/Overseas locations were combined within the Marine Corps, within the Coast Guard, and within the AGR/TARS.
- Since the Coast Guard does not use the "Other" category when defining race/ethnicity groups, this level was excluded from the stratification for the Coast Guard.
- The enlisted categories E5 to E6 and E7 to E9 were combined for the Coast Guard, and the enlisted categories E1 to E3 and E4 were combined for the AGR/TARS.

¹ For ease of reference, particularly in tables, the group Native American & Alaska Native is some times referred to as just Native American. Even when not specified, the group "Native American" should always be assumed to include Alaska Natives.

Final Strata Definitions

The final strata definitions are listed in Appendix B, Table B-2. A total of 255 strata were constructed. The "unknown" stratum (stratum 255 in Table B-2) contains persons for whom one or more of the stratum dimensions of race/ethnicity or location was missing from the source information.

Sample Size and Allocation

After the strata were constructed, domains and their associated precision constraints were defined. Precision requirements were set for selected domains to allow in-depth analysis for the overall active-duty population and some depth of analysis for other domains. More specifically, the survey precision requirements were set for domains that would facilitate analyses for each racial/ethnic group (i.e., non-Hispanic Whites, non-Hispanic Blacks, Hispanics, Asian and Pacific Islanders, Native Americans, and Others) separately for the active strength personnel (i.e., active-duty personnel including AGR/TARs) by each level of the stratification variables (i.e., Service, location, and paygrade groups), and by selected crossings of these variables. Special attention was given to allow for Service-level analyses.

As noted earlier, the final sample size was increased from the originally targeted 60,000 in order to increase precision in specific domains, such as Europe, Asia, officers, Native Americans, and minority groups within locations.

For *EOS*, key parameters were defined as the proportions of persons (prevalence rates) belonging to specified domains who would report having experienced one or more of the behaviors defined in the survey as racial/ethnic harassment or discrimination. Prevalence rates of 0.5 were used, and the variance constraints imposed on the prevalence estimates were computed from confidence interval half-widths specified for the key domains.

Cost Model

Once the precision requirements were defined, the total sample size and its allocation to the design strata were determined such that the imposed variance constraints were satisfied for the least cost. To this end, equations were developed that describe the variable survey cost and the variances of sample estimates of the key reporting domains. The equations expressed the cost and the variances in terms of the key features of the sampling design (constants in the equations) and the stratum-level sample sizes (the unknowns in the equations). The allocation solutions were obtained by solving the equations simultaneously subject to the variance constraints. The allocation procedure was first described by Chromy (1987).

A cost model is generally developed by determining the per sampling unit cost of each of the activities to be accomplished during the survey. The list of activities, although subjective in nature, must seek to be exhaustive if the model is to describe or predict accurately the actual cost of the survey. Once the activity list is compiled, the cost of each item is partitioned into coefficients associated with the salient features of the total design, including both the sampling and the data collection designs. For example, data collection costs may be different in different

design strata. In the case of multistage and multiphase designs, the costs will depend on the stage and phase of sampling. Fixed costs (those that are not affected by changes in the number and allocation of sampling units) must be clearly separated from variable costs. Fixed costs disappear upon taking the derivatives of the cost equations and do not enter into the determination of the allocation solutions.

The set of survey activities can be categorized according to whether an activity is associated with:

- sampling frame construction and stratification,
- sample selection,
- instrument development,
- data collection,
- data editing,
- data processing, and/or
- analysis and reporting.

For one-stage stratified design surveys like that used for the 1996 *EOS*, the costs associated with sampling frame construction and stratification and the costs associated with instrument development do not depend on the sample size and allocation and are therefore fixed costs. Sample selection costs do increase as the sample size increases but only marginally (because the greater part of the sample selection cost depends on the size of the sampling frame rather than the size of the sample). For one-stage stratified design surveys where the sample is selected from computer accessible files, most of the cost is incurred in the development of software to access the files and select the sample – an activity with fixed costs. Once the software is developed, the cost differential between a small and a large sample is easily ignored unless the sample size differential is extraordinarily large. Similarly, although analysis and reporting costs depend to some degree on the sample size, the difference is easily ignored unless the analysis procedures require that excessive attention be paid to the individual sample records. Otherwise, the major component of the analysis cost derives from setting up software to do tasks such as generate tables, run regressions, and plot graphs. Thus, analysis and reporting costs are also mainly fixed costs.

For the 1996 *EOS*, the expected variable survey costs depended almost entirely on the planned data collection, editing and processing activities. Additionally, per unit data collection costs would be positively related to the expected response rates in the different design strata. That is, follow-up mailings were planned for nonrespondents at specified times over the total data collection period. Data collection costs were consequently expected to be higher in those strata that would experience lower initial response rates than in those expected to have higher initial response rates. Conversely, data editing and processing costs would be higher in those strata that

experience higher rather than lower response rates because of the larger volume of material to be handled.

These considerations suggested a cost model of the following form:

$$C = \sum_h n_h \bar{C}_h$$

$$= \sum_h n_h (C_{1,h} + C_{2,h} + C_{3,h}),$$

where the subscript h denotes the design strata and,

n_h = the sample allocation made to the h -th stratum,

$C_{1,h}$ = the cost of the data collection (to an individual classified into the h -th stratum),

$C_{2,h}$ = the cost of editing a returned package,

$C_{3,h}$ = the cost of editing and processing a returned package.

The data collection cost coefficient for individuals classified into the h -th stratum is the quantity,

$$C_{1,h} = \frac{(C'_{1,h} + (1 - R_{1,h})C'_{2,h} + (1 - R_{1,h} - R_{2,h})C'_{3,h})}{(R_{1,h} + R_{2,h} + R_{3,h})}$$

where

$C'_{1,h}$ = the cost of an initial mailing to an individual classified in the h -th stratum,

$C'_{2,h}$ = the cost of the second mailing,

$C'_{3,h}$ = the cost of the third mailing,

$R_{1,h}$ = the expected response rate to the first mailing,

$R_{2,h}$ = the expected response rate to the second mailing,

$R_{3,h}$ = the expected response rate to the third mailing,

and the overall expected response rate within the h -th stratum is

$$\bar{R}_h = R_{1,h} + R_{2,h} + R_{3,h}.$$

The data collection, editing and processing activities were to be carried out by a contractor different from that used in designing the sample. Consequently, to preserve the confidential nature of the cost information, the dollar values for the C -coefficients were based on ranges provided by DMDC. In this respect, the absolute dollar values of the coefficients were less important for determining the sample allocation than they were for determining the operational survey costs. For the purpose of allocating the sample, relative costs sufficed and the lower endpoints of the ranges were chosen. The cost coefficients used for design purposes are:

Cost Coefficient	Costs for	<i>EOS</i>
$C'_{1,h}$	Initial mailout	\$2.35
$C'_{2,h}$	Second mailout	\$1.45
$C'_{3,h}$	Third mailout	\$1.45
$C_{2,h}$	Data editing	\$1.45
$C_{3,h}$	Data processing	\$2.27

The $C'_{1,h}$ -coefficient was intended to include costs associated with:

- reproducing and mailing the notification letter,
- reproducing and mailing the first wave (letter, questionnaire, and return envelope), and
- reproducing and mailing the reminder/thank you letter.

The $C'_{2,h}$ and $C'_{3,h}$ coefficient were intended to include costs associated with reproducing and mailing the packages for follow-up waves (cover letters, questionnaires, and return envelopes).

The $C_{2,h}$ coefficient included costs associated with:

- receipt control and reporting,
- scan coding the questionnaires,
- keying open ended responses, and
- transcribing comment sheets.

The $C_{3,h}$ coefficient included costs associated with

- constructing sample data files, and
- quality assurance procedures.

The expected response rates for the *EOS* were primarily based on response rates from the 1992 Active Duty Survey. The 1992 survey employed a stratified random sample of 75,345 regular active-duty members and 5,484 AGR/TAR members. Weighted population response propensities were estimated from two linear models that regressed the *EOS* stratifiers on a population weighted response flag from the 1992 Survey. The first model included five main effects (i.e., Service, location, paygrade, and race/ethnicity) and was used to estimate response propensities for AGR members. The second model combined main effects with two-way interactions and was used to estimate response propensities for the remainder of the active-duty members.

The Coast Guard was not included in the 1992 sample, and response propensities could not be estimated for them. Coast Guard response rates for the *1995 Gender Issues Form of the SAFS* showed that: (a) the Coast Guard and Air Force had similar response rates for White and Black military members, and (b) the Coast Guard and Army had similar response rates for all other races and ethnicities. Consequently the Air Force and Army response propensities were used for the corresponding Coast Guard strata.

These estimated response rates were then modified for use in the *EOS* because of the different nature of the two surveys. Specifically, 5% lower response rates were used for nonminorities, and 5% higher response rates were used for minorities. The distribution of expected response rates by design strata (i.e., the values \bar{R}_h , assumed for purposes of determining the sample allocation) is given in Appendix B, Table B-3, along with the distribution of the per unit stratum level cost coefficients, \bar{C}_h . The mailing level response rates for the initial mailout and the follow-up mailouts ($R_{1,h}$, $R_{2,h}$, and $R_{3,h}$ respectively) were apportioned as 60%, 30%, and 10% of the stratum-level rates, \bar{R}_h . That is, it was assumed that 60% of the responses in any stratum would come from the initial mailout, 30% would come from the second mailout, and 10% would come from the third mailout.

Variance Model

In this section the reporting domains are denoted using the subscript d . Define the indicator variables,

$$\begin{aligned} \delta_{d,h,i} &= 1 && \text{if the } i\text{-th individual in the } h\text{-th stratum belongs to the } d\text{-th domain,} \\ &= 0 && \text{otherwise,} \\ \delta_{h,i} &= 1 && \text{if the } i\text{-th individual in the } h\text{-th stratum reports having experienced at least} \\ &&& \text{one of the behaviors defining racial/ethnic harassment or discrimination,} \\ &= 0 && \text{otherwise.} \end{aligned}$$

Then the total members of the domain who report having experienced at least one of the behaviors is the quantity,

$$N_d P_d = \sum_h \sum_{i=1}^{N_h} (\delta_{h,i}) (\delta_{d,h,i}),$$

where $i = 1, 2, \dots, N_h$ denotes the individuals classified into the h -th stratum. At the population level, the relative number of individuals in the domain who report having experienced at least one of the behaviors is,

$$P_d = \sum_h \frac{N_h}{N_d} P_{d,h},$$

where,

$$P_{d,h} = \left(\frac{1}{N_h} \right) \sum_{i=1}^{N_h} (\delta_{h,i}) (\delta_{d,h,i}).$$

Denote the sample estimate of the relative domain size by,

$$\hat{P}_d = \sum_h \frac{N_h}{N_d} \hat{P}_{d,h},$$

with variance,

$$Var\{\hat{P}_d\} = \sum_h \left(\frac{N_h}{N_d} \right)^2 Var\{\hat{P}_{d,h}\},$$

where,

$$Var\{\hat{P}_{d,h}\} = \left(\frac{N_h - n_h}{n_h N_h} \right) P_{d,h} (1 - P_{d,h}).$$

The variance constraints take the form,

$$Var\{\hat{P}_{d,h}\} \leq K_d = \frac{\{CI\{\hat{P}_d\}\}^2}{1.96}$$

where the values K_d are chosen by the investigator. Specifically,

$$CI\{\hat{P}_d\} = 1.96 \sqrt{Var\{\hat{P}_d\}}$$

are the confidence interval half-widths listed in Appendix B, Table B-1, under the column heading "Precision Constraint."

Allocation Solutions

The allocation solutions were obtained by minimizing the objective function,

$$O(n_h, \lambda_d) = C + \sum_d \lambda_d \left(\text{Var}\{\hat{P}_d\} - K_d \right).$$

The form of the objective function is design specific. For this survey (employing stratified random sampling) the objective function is given by,

$$O(n_h, \lambda_d) = \sum_h n_h \bar{C}_h + \left(\sum_d \lambda_d \sum_h \left(\frac{N_h}{N} \right)^2 \left[\frac{N_h - n_h}{n_h N_h} \right] P_{d,h} (1 - P_{d,h}) - K_d \right).$$

The values λ_d are generalized Lagrange multipliers, one for each of the imposed variance constraints.

Taking the derivatives $\frac{\partial O(n_h, \lambda_d)}{\partial n_h}$ and equating to zero yields equations of the form,

$$\frac{\partial C}{\partial n_h} = - \sum_d \lambda_d \frac{\partial \left(\text{Var}\{\hat{P}_d\} \right)}{\partial n_h} \quad (1)$$

These equations are solved numerically to obtain the solutions n_h^* . At the points n_h^* there exist values of the Lagrange multipliers λ_d^* such that Equation 1 holds and additionally,

$$\text{Var}\{\hat{P}_d\} \Big|_{n_h^*} \leq K_d, \quad (2)$$

$$\lambda_d^* \geq 0 \quad (3)$$

$$\lambda_d^* \left(\text{Var}\{\hat{P}_d\} \Big|_{n_h^*} - K_d \right) = 0. \quad (4)$$

Equations 1 through 4 are the Kuhn-Tucker necessary conditions.

For this survey the solution took the form,

$$n_h^* = \sqrt{\frac{\sum_d \lambda_d^* \left(\frac{N_h}{N} \right)^2 P_{d,h} (1 - P_{d,h})}{\bar{C}_h}}$$

and was found using an iterative numerical procedure. If the initial values of the Lagrange multipliers used to start the procedure are set to

$$\sqrt{\lambda_d} = \frac{\sum_h \frac{N_h}{N} \left(\sqrt{P_{d,h}(1-P_{d,h})} \right) (\sqrt{C_h})}{K_d},$$

then a comparison of the initial and final values of the Lagrange multipliers will identify those variance constraints that are driving the solutions and, by implication, the variable survey costs. Those constraints that are driving the costs will have final Lagrange multipliers nearly equal to these initial values, giving ratios close to one. Often a small relaxation of one or more of the identified constraints can produce impressive reductions in the cost of the survey. Constraints that are satisfied coincidentally with other constraints will have final Lagrange multipliers equal to zero.

The allocation solutions obtained are listed in Appendix B, Table B-4. The allocation solutions are expressed in terms of the number of observations needed to (jointly) satisfy the variance constraints. The sample size selected from each stratum was obtained by inflating these numbers as necessary to allow for nonresponse and other operational considerations.

Expected Performance of the Sample

The precision requirements listed in Table B-1, Appendix B, were determined over several iterations. Calculations were performed with an early version of the sample allocation program developed for DMDC by the Research Triangle Institute (Kavee & Mason, 1997). The initially specified requirements proved too restrictive to be practical. At each iteration, those variance constraints that were the major determinants of cost were identified and progressively relaxed until a set of constraints was developed that would provide both an informative and an affordable study.

Those constraints that were the major determinants of the final allocation solutions are listed in Tables B-5, Appendix B. The constraints that were the most important determinants of the allocation solutions tend to be associated with domains defined as second-order interactions (i.e., cross classifications of three domain variables, e.g., domain number 102, consisting of non-Hispanic Black E1-E4's in the Coast Guard). This result is not surprising in that these constraints were imposed on small subdivisions of the total population. By contrast most of the main effect constraints (i.e., domains defined by a single variable) have Lagrange multiplier ratios of zero, indicating that the constraints were coincidentally satisfied with the imposition of other constraints.

Because the imposed constraints are inequality constraints, the average performance of the sample tends to be better (i.e., tends to have smaller confidence interval half-widths) than is suggested by the constraints themselves. Comparison of the columns headed "Precision Constraint" in Table B-1 with the columns headed "Expected Precision" in Table B-5 shows that, except for those domains with large Lagrange multiplier ratios, the expected values of the confidence interval half-widths are less than the imposed values.

Table B-5 also shows the design effects associated with the prevalence estimates for each of the domains. The design effects listed in the tables show the relative efficiency of the design for each of the domain estimates. The design effect is computed as the sampling variance given the design (including the sample allocation) divided by the variance that would be obtained using a simple random sampling design with the same number of observations. Components of the design effect include a stratification effect, a finite population effect due to sampling without replacement, and an unequal weighting effect due to the disproportionate sample allocation. By far the most important of these component effects is the unequal weighting effect, which acts to increase the variances relative to those that would be obtained with a simple random sample of the same size.

Design effects judged to be excessively large provide some guidance for modifying either the design strata or the domain constraints or both. For example, the prevalence estimate for domain number 14, (i.e., officers), has an associated design effect greater than 4. The efficiency of the design for this main effect constraint could perhaps be improved in future surveys by removing the location strata. Alternately, or in addition, the variance constraints imposed on the officer higher-order interactions could be relaxed even further. Of course, such changes would be made only if the affected domains need not be estimated with as much precision as this design.

Revised Allocation for the Survey

The Kuhn-Tucker solution provides an optimal solution for the number of observations required to meet the precision constraints. Strata-specific response rates were then used to compute sample sizes to provide, in expectation, the numbers of observations specified by the sample allocation. The stratum-level sample sizes for the survey are listed in Table B-6, Appendix B.

In strata which were too small to support the allocation of the sample, the total number of persons in the strata was selected into the sample. To the extent that there were not large enough populations in strata to obtain the respondents required to meet the calculated precision estimates, the sample design was not effective in meeting precision constraints for domains affected by strata smaller than the calculated sample sizes. The effects of this are trivial except for a domain where across the strata tapped by the domain, the calculated sample sizes are much larger than the strata populations. For the EOS the effects were nontrivial for almost all domains defined by Native Americans & Alaska Natives where the calculated sample sizes exceeded the available population in 24 of 43 strata. This caused the sample size allocation (5562) to exceed the available population by 16% (909). Compounding the problem, lower than expected response rates further reduced the required available population in 13 of the 43 strata. This caused the allocation to exceed an additional 6.2% (346) of the required available population. The design for future surveys could be improved by modifying the software to correct for the effects of strata where the allocation is larger than the population.

Sample Selection

The sample of 76,754 military members was distributed as shown in Table B-6, Appendix B. The sample was selected with equal conditional probabilities, given the stratum, and without

replacement, from person-level records contained in the April 1996 AMDF and the April 1996 RCCPDS. A stratum-level lookup table that mapped the relevant variables in the source information records into the proper stratum was used in selecting the sample. The stratum-level sample size information was also provided in the lookup file.

The steps in the sample selection procedure were as follows:

- Each record in the source file was classified into the appropriate stratum using the lookup table.
- Seven digit random numbers were generated in the interval $[0, 1]$ and associated with each of the records in a stratum. The use of seven digits in the random numbers allowed with a high probability that each number would be unique.
- The file was put in random order by sorting the records by their associated random numbers.
- Denote the stratum-level sample sizes in Appendix B, Table B-6 by n_h with the subscript $h = 1, 2, \dots, 255$ denoting the strata. Because the records had been placed in random order, the first n_h records comprised the sample from the h -th stratum for the survey.
- Assign a unique number (DMDC_ID) to each record as it is selected into the sample. Because the records had been placed in random order, this case identification number used throughout the study is a random variable and not associated with any characteristic of the individual.

Missing Data Compensation

A distinction is made in this section between *sampling weights* and *analysis weights*. Sampling weights are defined as the inverses of the expected frequencies with which individuals are selected into the sample. The sampling weights are subsequently modified, primarily to compensate for the missing data patterns actually experienced. The modifications are applied to the sampling weights to produce the analysis weights, which are then used to compute the parameter estimates and their associated variance estimates.

The approach used to adjust the weights was to perform a CHAID analysis to determine variables and interactions related to the likelihood of nonresponse. The segments determined by CHAID were then used along with variables that are important analysis domains in a logistic regression model.

Performing nonresponse adjustments using logistic modeling of *unit response propensity* has become increasingly more popular because of the potential increase in bias reduction achieved with such an adjustment over the commonly used weighting class approach (e.g., see Folsom, 1991; Iannacchione, Milne, & Folsom, 1991; Rizzo, Kalton, Brick, & Petroni, 1994). The zero-one response indicator is regressed on a set of independent variables which are available for both respondents and nonrespondents. These independent variables are chosen because they are related to the likelihood of response. The predicted value obtained from the regression equation is the estimated response probability for population members with the same values of the independent variables. The inverse of this estimated probability is used to adjust the sampling weight of the respondents. This procedure is referred to as a *response propensity weight adjustment*.

As noted in Appendix E (which gives mathematical expressions for obtaining estimates of totals, means, and regression coefficients), sample estimates of domain sizes are obtained by summing the sampling weights over the sample individuals that belong to the domain. Clearly if some of the domain members fail to respond, the sum of the sampling weights over the set of respondents will underestimate the size of the domain. The logistic adjustment, similar to *weighting class adjustments*, multiply the sampling weights for respondents by an adjustment factor to produce analysis weights that, when summed over respondents, equal the sum of the sampling weights for respondents and nonrespondents. For weighting class adjustments, the adjustment factors are computed within classes constructed with the objective of placing nonrespondents in the same class with respondents thought to have substantially similar response variable values. Classes are typically constructed from demographic variables known from previous research to be associated with differences in survey response rates and with differences in responses on key items in the survey.

Subsections in this section describe construction of the adjusted weights using logistic modeling, describe the procedures to determine the variables to be included in the model, and compare and contrast the modeling procedure with the weighting class approach.

The notation used in this section builds on that used in the Sampling Design section. Given the design, the sampling weights are the quantities

$$w_{h,i} = \frac{N_h}{n_h}, \quad i = 1, 2, \dots, n_h.$$

That is, for each individual classified into the h -th stratum, the sampling weight is simply the total number of individuals in the stratum divided by the stratum-level sample allocation. Using this notation, an estimated total for domain d is written as,

$$\hat{T}_{d,y} = \sum_h \sum_{i=1}^{n_h} \delta_{d,h,i} w_{h,i} y_{h,i}.$$

The subscript, d , denotes a particular domain of interest, and,

$$\begin{aligned} \delta_{d,h,i} &= 1, \text{ if the } i\text{-th unit in the } h\text{-th stratum belongs to the } d\text{-th domain,} \\ &= 0, \text{ otherwise.} \end{aligned}$$

The total defines some variety of parameters depending on the response variable values $y_{h,i}$ (as described with examples in Appendix E of this report).

However, because of nonresponse, observations are obtained for only $i' = 1, 2, \dots, r_h \leq n_h$ individuals. Clearly, at least for values of $y_{h,i} = 1$, the quantity

$${}^r\hat{T}_{d,y} = \sum_h \sum_{i'=1}^{r_h} \delta_{d,h,i'} w_{h,i'} y_{h,i'}, \quad (5)$$

that is the sum of the sampling weights over respondents, underestimates $\hat{T}_{d,y}$ whenever $r_h < n_h$. This requires some type of adjustment.

Nonresponse is defined as occurring whenever one or both of the values $\delta_{d,h,i}$ or $y_{h,i}$ are missing or unknown such that the product $\delta_{d,h,i} \times w_{h,i} \times y_{h,i}$ cannot be formed. If, for example, the d -subscript identifies the domain of survey-eligible non-Hispanic Black officers, then the i -th sample individual is a nonrespondent if at least one of a person's eligibility status, race/ethnicity, and paygrade is indeterminate (i.e., the value of $\delta_{d,h,i}$ is unknown) or a value is not obtained for the person's response variable (i.e., the value of $y_{h,i}$ is unknown). Further note that, if the i -th individual is known to be ineligible, then, because $\delta_{d,h,i} = 0$, the value of the product $\delta_{d,h,i} \times w_{h,i} \times y_{h,i} = 0$ (i.e., is known), and the individual is by definition a respondent.

Response Propensity Weight Adjustments

Nonresponse adjustments may be considered in the context of multiple regression where the zero-one response indicator is regressed on a set of independent variables which are available for both respondents and nonrespondents. The predicted value obtained from the regression is the estimated response probability for population members with the same values of the independent variables. The inverse of this estimated response rate is used to adjust the sampling weight of the respondents. The EOS data set was an ideal situation in which to use response propensity modeling because of the large number of characteristics available for both respondents and nonrespondents from the military personnel files.

When the predicted response probabilities are used for nonresponse adjustment, logistic regression models are preferred to linear regression models. With the logistic model, the predicted probabilities will necessarily range between zero and one.

There are numerous advantages to using this modeling approach for calculating weight adjustments including:

- The basic idea of this modeling approach is to extend the group-level adjustment of the weighting class approach to person-level adjustments derived from the model's predicted response propensities.
- These models preserve totals of main effect explanatory variables without necessarily preserving the multi-way cross-classification total of main effects. The multi-way cross classification totals that are controlled depends on which interaction terms are included in the model. In contrast to the simple weighting class adjustment procedure, the advantage to this approach is that a larger number of main effect variables can be used in the adjustment procedure.
- Similar to other model-based analyses, this modeling approach allows one to use a large number of potentially significant variables including continuous variables, it allows one to include complex interactions, and it allows one to formally test the ability of the adjustment variables to explain response propensity variation.

Let $\delta_{r,h,i} = 1$ if sampled individual i responds, and 0 otherwise. Also, let $X_{h,i}$ be a vector of characteristics for the i -th individual, $X_{h,i} = [1, X_{h,i,1}, X_{h,i,2}, \dots, X_{h,i,m}]$. Assume that the following model holds for the probability that sample member i responds:

$$\Pr[\delta_{h,r,i} = 1 | X_{h,i}, \beta] = \left(1 + e^{-X_{h,i}\beta}\right)^{-1} = \gamma_{h,i}$$

where β is a vector of logistic regression coefficients, $\beta = [\beta_0 \ \beta_1 \ \dots \ \beta_m]^t$. The logistic regression coefficients are estimated by iteratively solving the system of estimation equations²

$$\sum_h \sum_i w_{h,i} / \hat{\gamma}_{h,i} \delta_{h,r,i} = \sum_h \sum_i w_{h,i} X_{h,i} = {}^w T_0 \quad (6)$$

where $w_{h,i}$ is the sample weight for sample member i and $\hat{\lambda}_{h,i}$ is the predicted probability of response for the i th individual. ${}^w T_0$ denotes $\sum_h \sum_i w_{h,i} X_{h,i}$ and is a column vector of weighted totals. Let $\hat{\lambda}_{h,i} = 1 / \hat{\gamma}_{h,i}$.

The response probability adjusted weight is computed by dividing the unadjusted weight by the estimated probability of response. That is,

$${}^r w_{h,i} = w_{h,i} \delta_{r,h,i} / \hat{\gamma}_{h,i} = w_{h,i} \delta_{r,h,i} \hat{\lambda}_{h,i}. \quad (7)$$

Note that the adjusted weight of sample members who do not respond is zero.

For any zero-one predictor $X_{h,i,k}$ the estimation equations require that

$$\sum_h \sum_i {}^r w_{h,i} X_{h,i,k} = \sum_h \sum_i w_{h,i} X_{h,i,k} = {}^w T_0.$$

Because the first element of $X_{h,i}$ is uniformly 1, the constraint equations force the adjusted weight sums for responding sample members to equal the corresponding unadjusted weight sums across all sample members. In addition, the equality of weight sums holds for any sample subset identified by a zero-one indicator in $X_{h,i,k}$, and the unadjusted and adjusted weighted total and mean for any continuous $X_{h,i,k}$ will be equal.

Choice of Variables

The variables considered for inclusion in the logistic model included those variables used to define the strata for the survey (Service, component, race/ethnicity, location, and paygrade). The strata-defining variables were a logical choice since the strata were originally constructed from variables thought to be related to survey response propensity and/or important differences in the subject matter. Other characteristics (education level and marital status) identified by Rizzo and Nixon (1996) in a 1992 DoD Survey of Reservists were considered. Gender, deployment status, Hispanic occupation density, Black occupation density, and minority occupation density were included because of their potential analytic use. Finally, finer divisions of some of the

² The solution equations for the weight adjustment algorithm differ from the standard design-weighted logistic regression in that the adjusted weights $w_{h,i} / \hat{\gamma}_{h,i}$ are substituted for the weights in the iterations in the equations.

variables used to define strata, such as individual levels of paygrade and more detailed location were considered. A summary of the variables considered is:

- Service (Army, Navy, Marine Corps, Air Force, Coast Guard)
- Component (Regular active duty, Reservist, National Guard)
- Race/ethnicity (White non-Hispanic, Black non-Hispanic, Hispanic, Native American & Alaska Native, Asian & Pacific Islander, Other)
- Region of the US and world (Northeast, North Central, South, West, Europe, Asia or Pacific Islands, Other)
- Marital status (Single or unknown, Married)
- Gender (Male or unknown, Female)
- Deployment status (Deployed, Not deployed)
- Paygrade (individual levels E1 - O6, and unknown)
- Minority occupation density (Low, High; for enlisted low was 8.1% - 33.2% and high was 33.5% - 53.0%, for officers low was 0.0% - 14.8% and high was 15.0% - 34.7%)³
- Black occupation density (Low, High; for enlisted low was 2.4% - 22.3% and high was 22.8% - 38.1%, for officers low was 0.0% - 8.4% and high was 8.4% - 21.0%)
- Hispanic occupation density (Low, High; for enlisted low was 8.1% - 33.2% and high was 6.5% - 8.5%, for officers low was 0.0% - 14.8% and high was 15.0% - 34.7%)

An initial assessment of whether a variable might be useful was based on looking at response rates in different levels of the variables, both overall and within levels of Service, race/ethnicity, and paygrade groups. Candidate variables needed to have differing response rates in the different levels. This examination indicated that marital status and education level would possibly be important predictors. Most of the other variables also showed differences in response rates at some Service, race, or paygrade group. This analysis indicated that interactions might be present. It also indicated little symmetry across the Services and race/ethnicity groups. For example, the minority density variables showed differences in response rates for some race groups but not others, and gender appeared to be a potential predictor for some Services but not others. The analysis also showed that total and respondent sample sizes were too small in some Service by race groups for all variables to be useful. For example, deployment status was useful for the

³ Occupation density refers to the proportion of members within a particular occupation that belong to a racial or ethnic group. Gaps in the ranges occur because distributions were not continuous.

Navy but not the Coast Guard because few if any Coast Guard personnel are deployed, and gender was useful for the Army but not the Marine Corps.

The next step was to perform a CHAID analysis on the potential predictor variables to determine interactions to be included in the model. A CHAID analysis divides the data into segments which differ with respect to the response indicator. That is, the data set is progressively split into categories that are as different as possible. The segmentation process divides the sample into groups based on categories of the most significant predictor of response. It then splits each of these groups into smaller subgroups based on other predictor variables. It also merges categories of a variable that were found to be insignificant. This merging and splitting process continues until no more statistically significant predictors are found or until some other specified stopping rule is met. A rule used for the *EOS* survey was that sample sizes in each of the final segments needed to be at least 100.

CHAID analyses were performed separately for each Service. CHAID was instructed to consider race/ethnicity as the predictor at the first step. Groupings of paygrade were the variables generally found by CHAID to be most predictive. (An earlier CHAID run which did not specify that race/ethnicity be considered first identified paygrade groupings followed by race/ethnic groupings to be the most predictive.) An exception was that level of education was the most important predictor for Hispanics in the Air Force.

CHAID identified 182 subgroups of the population. A small amount of additional subdividing was manually performed on some of the segments to prevent levels of stratification from being split and combined in ways that would further increase the variability in the adjusted weights. For example, CHAID combined the West region of the US with the Overseas region, and this segment was manually split into two, one for the West and the other for Overseas. Similarly, CHAID sometimes combined paygrades E8 and E9 with the officers and in this case the segment was split into two. When this splitting resulted in small sample sizes, the small segment was combined with another segment in the same sampling strata. As a result of this process the sample was divided into 212 disjoint segments determined by CHAID to have differing response rates.

These segments were coded as 0 or 1 indicator variables and were used along with the race/ethnic group by paygrade and the race/ethnic group by location (US and Overseas) interactions as independent variables in a response propensity model. These interaction terms were included even when CHAID did not identify them as important since they define important analysis domains. Including these terms in the models insured that the response-adjusted weights would sum to the original sample weights within levels of race by paygrade and race by location. The CHAID segments could have been used as weighting classes (as was used by Rizzo & Nixon, 1996), but had this been done, response-adjusted weights would have summed to the original sample weights only for those domains defined by the weighting class segments. Separate models were run for each of the Services (Army, Navy, Marine Corps, Air Force, Coast Guard, and AGR/TARS). Tables B-7 to B-12 give the indicator variables included in the final models for each of the Services; these tables also give the weighted response rate for the subgroup defined by each indicator variable. The modeling procedure was used to adjust the weights of respondents for all but the unknown stratum; a single ratio adjustment was used there.

The response probability adjusted weights were examined for excessive variation. This was done by looking at the distribution of the adjustment factors, and calculating the *unequal weighting effects* for both the unadjusted and adjusted weights.⁴ Table 3 presents the unequal weighting effects and the minimum and maximum adjustment factors for the response-adjusted weights, overall and by Service. The unequal weighting effect is also presented for the original sampling weight (for respondents). The largest adjustment factor was 5.96; the large adjustment factors were for the E1-E3s, where response rates were in the 25 to 35% range.

Table 3.
Summary of Unequal Weighting Effects and Adjustment Factors for the Sampling Weights, Response-adjusted Weights, and Poststratified Weights

	Total Sample	Army	Navy	Marine Corps	Air Force	Coast Guard	AGR/ TARs
Original Sample Weights							
Unequal Weighting Effect	3.31	3.17	3.27	2.46	2.95	2.92	2.39
Response-adjusted Weights							
Unequal Weighting Effect	3.51	3.52	3.47	2.71	3.06	2.64	2.49
Minimum Adjustment Factor	1.04	1.06	1.11	1.18	1.04	1.25	1.08
Maximum Adjustment Factor	5.92	5.86	5.92	4.03	2.47	3.01	3.29
Poststratification Adjusted Weights							
Unequal Weighting Effect	3.47	3.50	3.44	2.69	3.05	2.63	2.48
Minimum Adjustment Factor	0.97	0.98	0.97	1.01	0.99	0.98	1.00
Maximum Adjustment Factor	1.05	1.03	1.04	1.05	1.05	1.01	1.05

For variance estimation, original sampling strata with fewer than 25 respondents were collapsed. Table B-13 presents the variance estimation strata, number of respondents, and response rates. Service, race/ethnicity and officer/enlisted distinctions were preserved in constructing the combinations. For the AGR/TARs, persons in the other race group were combined with Asian/Pacific Islanders.

Comparison with the Weighting Class Adjustment Procedure

This section describes similarities and differences in the weighting class and response propensity modeling adjustment procedures. Like response propensity adjustments, weighting class adjustments multiply the sampling weights for respondents by an adjustment factor to produce analysis weights that, when summed over respondents, equal the sum of the sampling weights for respondents and nonrespondents. The weighting class adjustment factors are computed within classes constructed with the objective of placing nonrespondents in the same class with respondents thought to have substantially similar response variable values. Classes are

⁴ The unequal weighting effect is sometimes referred to in the literature as $1 + CV^2$, where CV is the *coefficient of variation* of the weights. The unequal weighting effect is a component of the survey design effect.

typically constructed from demographic variables known from previous research to be associated with differences in survey response rates and with differences in responses on key items in the survey. Similar considerations are used to determine the variables to be included in the model for response propensity. The segments identified by CHAID could be used as weighting classes since they subdivide the population into classes.

The goal with both procedures is for the adjustment to reduce the bias in estimates of the domain parameters and to adjust the estimated size of the domain. Since more variables can be included in the model than can be used as classes, the adjusted weights derived from the modeling procedure have the potential for greater reduction in the nonresponse bias.

Notationally, the weighting class adjustment is the sum of the weights over all of the sample individuals in a class divided by the sum of the weights over the respondents in the same class. That is, denoting a class using the subscript, c , the adjustment for the i -th respondent in the h -th stratum is

$$a_{c,h,i} = \frac{\sum_h \sum_{i=1}^{n_h} \delta_{c,h,i} w_{h,i}}{\sum_h \sum_{i=1}^{n_h} \delta_{c,h,i} \delta_{r,h,i} w_{h,i}}, \quad (8)$$

where,

$\delta_{c,h,i} = 1$, if the i -th individual in the h -th stratum is classified into the c -th weighting class,

$= 0$, otherwise,

$\delta_{r,h,i} = 1$, if the i -th individual in the h -th stratum is a respondent,

$= 0$, otherwise.

If, for example, classes were defined by race (say non-Hispanic White versus other), then a race/ethnicity-specific adjustment factor would be computed by separately summing the sampling weights for all of the non-Hispanic Whites and all of the others in the sample and dividing each sum by the corresponding sum of the sampling weights for respondents.

Then the adjusted analysis weights,

$${}^r w_{c,h,i} = a_{c,h,i} w_{h,i} \delta_{c,h,i} \delta_{r,h,i}, \quad (9)$$

computed by multiplying the sampling weights by the appropriate adjustment, are used in place of the sampling weights in the estimation procedures described in the Appendix E of this report. The adjustment factor $a_{c,h,i}$ plays a role comparable to $\lambda_{h,i}$ from Equation 6. A difference is that

weighting class adjustments are applied to all individuals in a class, but response propensity weight adjustments are applied to individual sample members.

Weighting classes partition the sample in the sense that all individuals are accounted for in the set of classes, and an individual belongs to only one class. For example, if classes are formed by race and Service, then it is necessary to use the full cross of race and Service as classes. This is not the case with response propensity modeling, where the variables could be entered as main effects only. For the *EOS* weights, the CHAID segments could have been used for weighting classes, but the model allowed additional terms (race by paygrade and race by region) to be included as well.

The unequal weighting effect using the CHAID and response propensity modeling procedure would be expected to be larger than when a weighting class adjustment, using the strata as classes, was used. This is because the segments created by CHAID split the sampling strata. As a comparison, weight adjustment factors were calculated for *EOS* using a weighting class adjustment with classes defined by the variance estimation strata in Table B-17. The unequal weighting effects, had this adjustment been made, are given in Table 4. The unequal weighting effects are slightly larger using the CHAID/modeling approach compared to the weighting class adjusted weights (3.51 versus 3.43), and the range of the adjustment factors is greater. This table also presents correlations between the two sets of weights and adjustment factors. Correlations between the weights are high (0.98 or higher), and relatively high for the adjustment factors (0.85 or higher).

This analysis shows that the nonresponse adjustments from the two procedures are similar. This is likely because the important determinants of nonresponse (Service, paygrade, and race) are used in both, and because the weight sums are being adjusted to totals by race and paygrade, and race and region. The CHAID/modeling approach leads to slightly higher variances, but the hope is that the bias will be reduced in the estimates due to the additional variables used for adjustments and that this will result in a smaller *mean square error*.

Table 4.
Unequal Weighting Effects and Adjustment Factors, Using a Weighting Class Adjustment for Nonresponse, with Classes Formed by Sampling Strata

	Total Sample	Army	Navy	Marine Corps	Air Force	Coast Guard	AGR/ TARs
Unequal Weighting Effect	3.43	3.40	3.37	2.71	3.03	2.64	2.44
Minimum Adjustment Factor	1.18	1.26	1.18	1.30	1.18	1.25	1.18
Maximum Adjustment Factor	4.05	3.59	4.05	4.03	2.28	3.01	2.94
Correlations Between:							
Weighting Class Weight and Response Propensity Adjusted Weight	0.983	0.978	0.979	0.999	0.992	0.999	0.985
Weighting Class Adjustment Factor and Response Propensity Adjustment Factor	0.935	0.898	0.918	0.987	0.853	0.988	0.869

Poststratification Adjustments

The final step in producing the analysis weights involved a post-stratification step to force selected sample estimates to equal known population totals. Notationally, the known population totals are denoted by the vector quantity

$$T_0 = [T_{1,0} \quad T_{2,0} \quad \cdots \quad T_{p,0} \quad \cdots \quad T_{P,0}]$$

The population counts used correspond to the source information used to construct the sampling frame, but updated to the time of data collection. Counts used for *EOS* poststratification are the Service/component-specific counts of persons in each of the race/ethnic groups (non-Hispanic Black, non-Hispanic White, Hispanic, Native American & Alaska Native, Asian & Pacific Islander, and Other) as of the end of September 1996, and are given in Table 5.

Poststratification adjustment factors taking the form

$$b_{p,h,i} = \frac{T_{p,0}}{\sum r w_{h,i} \delta_{p,h,i}} \quad (10)$$

where $\delta_{p,h,i} = 1$, if the i -th individual in the h -th stratum is classified into the p -th cell,

$= 0$, otherwise,

were computed and applied multiplicatively to the response-adjusted weights $r w_{h,i}$ given in Equation 7. That is, the adjustment factor for respondents in the p -th class was the ratio of the known total in the class to the response-adjusted weights in the class. The poststratification adjustment factors were all close to 1, indicating that there had been little change in the size of the population between the time of sample selection and the beginning of data collection. Table 3 presents the minimum and maximum poststratification adjustment factors and unequal weighting effect for the final set of weights.

As mentioned above, the poststratification adjustment factors multiply the response-adjusted weights from Equation 7, $r w_{h,i}$, making the final analysis weights

$$^f w_{p,h,i} = r w_{h,i} b_{p,h,i} \delta_{p,h,i}$$

The estimation procedures described in Appendix E apply, using the final weight $^f w_{p,h,i}$ and summing over respondents.

Table 5.
Poststratified Totals - Counts as of September 1996

Service	Race/Ethnicity						Total
	White Non Hispanic	Black Non Hispanic	Hispanic	Native American	Asian/Pacific Islander	Other	
Army	297,358	130,392	27,918	3,077	11,365	15,413	485,523
Navy	284,187	70,924	30,735	2,536	21,803	1,461	411,646
Marine Corps	122,783	27,431	18,008	1,499	3,245	1,911	174,877
Air Force	297,806	56,964	15,272	2,042	8,031	4,607	384,722
Coast Guard	28,353	2,275	2,011	781	768	0	34,188
AGR/TARS	49,756	8,377	3,443	535	1,368	435	63,914
Total	1,080,243	295,363	97,3887	10,470	46,580	23,827	1,554,870

Performance Rates

It is important to examine the performance rates for surveys to judge the success of the survey effort and to plan for future survey efforts. In this section, response rates are provided for comparison of the performance of this survey effort with other survey efforts and to provide information for planning future surveys.

A number of different types of survey performance rates can be computed, with the difference in many of the rates being in how survey ineligibles are treated. The Council of American Survey Research Organizations (CASRO, 1982) noted that varying operational definitions of response rates can lead to difficulties in interpreting the results of a survey. To address this problem, CASRO formed a task force to recommend guidelines for standardizing the operational definitions of response rates. Beginning in 1995, DMDC standardized its methods for calculating response rates, using procedures closely patterned after those advocated by CASRO. More specifically, the new DMDC procedures closely follow CASRO's Sample Type II design. The CASRO approach corrects for ineligibility in both the numerator and denominator of the rate, and is referred to in this report as the *eligibility adjusted response rate*. Another type of response rate, which has uses because of its analogy to nonresponse weight adjustments and nonresponse analysis, treats known ineligibles as respondents in the numerator of the rate; this calculation is referred to as the *response rate* in this report. Estimates of both rates for EOS are given in this section.

The last portion of this chapter analyzes the demographic characteristics of respondents and nonrespondents.

Eligibility Adjusted Response Rate (CASRO)

The value given for the response rates in most of the *EOS* reports is the eligibility adjusted response rates as recommended by CASRO. These rates were corrected for ineligibility in the numerator and the denominator as recommended by CASRO, although the allocation of undetermined eligibility cases was made differently from that recommended by CASRO. CASRO recommends that nonrespondents for whom eligibility has not been determined be distributed to eligibility/ineligibility status using the eligibility rate among those for which a determination could be made. In the *EOS* an assumption has been made that all master file ineligibles were identified and therefore are excluded from the ineligibility rate used to estimate unidentified ineligibles.

The CASRO approach was used to classify nonlocatable sample members. That is, the 1,094 nonlocated sample members were classified as eligible or ineligible based on the proportion of self-report ineligibles found among located sample members. Among the located, responding sample members, 0.458% were self-reported as ineligible, and this percentage of the 1,094 nonlocated members were also assumed to be ineligible. CASRO's approach was also used to classify sample members who did not return a survey. That is, 32,241 sample members who did not return a survey were classified as eligible or ineligible based on the proportion of self-report ineligibles found among responding sample members. Consequently, 0.458% of the 32,241 with no survey return were assumed to be ineligible.

The overall weighted eligibility adjusted response rate (using sampling weights to compute ineligibility rates and overall rates) was 52.7%. The unweighted rate was 54.3%.

Response Rate

The sample allocation for this survey was determined in part by response rate information from previous DMDC surveys, specifically in the cost model, and in determining the sample sizes needed to provide the allocated number of observations in each of the design strata. For these purposes information was required on the response rate distribution in relation to the stratification variables. To be most useful in this context, the response rates used should be estimates of the corresponding population parameters, complete with associated variance estimates, as opposed to unweighted tabulations. That is, the response rates take the form of the estimated number of respondents in the population divided by the estimated size of the population. The procedures for obtaining the ratio and its standard error that are described in Appendix E apply, using the person-level variables defined by the products $\delta_{r,h,i} \times \delta_{d,h,i} \times y_{h,i}$. Note that, because the values of the response indicator variables $\delta_{r,h,i}$ are known for every individual in the sample, missing data problems do not arise when estimating response rates. By implication, the sampling weights rather than the analysis weights are used in the calculations. By definition, a nonrespondent is counted whenever one or both of the values $\delta_{d,h,i}$ or $y_{h,i}$ is missing or unknown. In summary, the *response rate* as used in this report was computed as

$$\text{response rate} = \frac{\text{eligible respondents} + \text{known ineligible}}{\text{total sample}}$$

This rate is easily computed and the definition is useful for nonresponse analysis. However, for surveys with a large number of known ineligible sample members, the rate computed using this definition may appear to overstate the success of the survey.

Estimated response rates and associated 95% confidence intervals for the *EOS* survey are provided in Appendix B, Table B-14. Unit-level rates are shown in the table for the variables used in defining the design strata. The estimated overall response rate was 55.0% with 95% confidence interval (54.4, 55.6). This definition and computation of the response rate is consistent with that used for the sample allocation for *EOS*, and for the nonresponse weight adjustments.

Comparison of Respondents and Nonrespondents

The objective in this section is to examine variables used in the CHAID analysis and weighting for significant associations with the experienced response rates. CHAID identified many interactions, but this section only looks at main effects to obtain a crude understanding of variables likely to affect response. This analysis does not replace or contradict the CHAID analysis since interactions can be present in the data, but main effects would not appear to be significant. Analyses are presented separately for each of the Services.

Tables B-15 to B-21 give the response rates for the entire sample and also separately by Service for each of the variables considered for the nonresponse weight adjustment. This was one of the analyses initially examined to determine variables that might be useful for nonresponse adjustments. These tables also present the weighted distributions of respondents, nonrespondents, and the total military population. Statistical tests of significance were performed to determine if there were differences in the response rates among different subgroups, and if there were differences in the distributions respondents and nonrespondents. Most of the variables showed significant differences at the 5% level; this is not uncommon with large surveys (Rizzo et al. 1994). The distributions in these tables indicate that compared to nonrespondents, respondents are more likely to be White rather than Black, in higher paygrades, are generally more likely to be married than single, are more likely to be not deployed than deployed, and have a higher level of education.

Response rates are related to the distributions, with rates increasing as paygrade or education level increased. Whites and some non-Black minorities had higher response rates than Blacks, married persons had higher rates than single persons, and persons not deployed had higher rates than those who were deployed. Among the regions of the US persons in the South generally had the lowest response rates (the South also contains the largest percentage of the military; 46.4% overall, from Table B-15). For the AGR/TARS, members of the National Guard responded at a higher rate than did members of the Reserves. Differences between rates for persons stationed in the US versus Overseas were small (although statistically significant). Results for the occupation density variables are inconsistent across the Services.

This univariate analysis indicates those subgroups of the population whose estimates have the potential to be most affected by nonresponse bias. Although this univariate analysis gives differences in response rates, it may be that differences in some variables can be explained by other factors. For example, married persons responded at higher rates than nonmarried persons, but married persons are also likely to be older than unmarried persons and in higher paygrades. Consequently, difference in rates between levels of marital status could be explained by differences in the paygrades.

The next step in the analysis was to run linear regression models, where the dependent variable was coded as 1 if the sampled persons was a respondent and 0 otherwise, and dependent variables were the variables presented in Tables B-15 to B-21. Linear regression was used instead of logistic regression since these analyses were exploratory. The results should not differ greatly from what logistic regression would show since the observed response rates were in the 20% to 80% range. Separate models were fitted for each Service. For race/ethnicity, White non-Hispanics were coded as the reference level since they are the largest group. The levels of paygrade used in the models were those used to define the sampling strata, with officers coded as the reference level. The South was the reference level for the region variable since persons stationed in that region are the largest group. Persons with less than a high school education and high school graduates were combined since there are so few persons with less than a high school education in the sample.

A model containing all the variables was run for each of the Services. The least significant variable was dropped from the model, and then the model was rerun. This process was continued

until only those variables significant at the 5% level were left in the model. The expanded region of the US or world variable was used first in the models, and if it was nonsignificant, it was replaced with the two-level US versus Overseas variable. The minority density variables were not included in the models because they form linear combinations with the paygrade variable; these variables would be better examined in models run separately for enlisted and officers.

Table 6 gives the variables found to be significant in the final models. Race/ethnicity, paygrade group, and level of education significant predictors for all of the Services. Black non-Hispanics were significantly less likely than White non-Hispanics to respond, in all the Services. Compared to White non-Hispanics these groups were less likely to respond: Asian/Pacific Islanders in the Army, Navy, Air Force, and AGR/TARs, Hispanics in the Marine Corps, and Native Americans in the Air Force. Enlisted paygrade groups were generally less likely to respond than officers, although the highest enlisted category (E7 to E9s) occasionally had rates similar to the officers. As was observed in the univariate analysis, persons with high school education or less or some college were significantly less likely to respond than persons with some college or more than college.

Other variables found to be significant predictors of nonresponse were marital status, gender, and location, although not all were significant at the 5% level for all Services. Unmarried persons in the Coast Guard were significantly less likely than married persons to respond, even after adjusting for other covariates. Males in the Navy and Air Force were significantly less likely to respond than females. Location and region showed significant differences at the 5% level only for the Navy and the AGR/TARs. Both variables were used in models for the Navy, where US based persons were less likely to respond than those overseas after adjusting for other variables, and persons in Europe and Asia or the Pacific Islands were more likely to respond than persons in the Southern US. For the AGR/TARS, persons in the North Central US and the West US were more likely to respond than persons in the South.

Table 6.

Significant Predictors of Response and p-values in Main Effect Models

Predictor Variable	Army	Navy	Marine Corps	Air Force	Coast Guard	AGR/TARs
Race/Ethnicity	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Paygrade group	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Marital status	ns	ns	ns	ns	0.0024	ns
Gender	ns	0.0311	ns	0.0009	ns	ns
Education	0.0000	0.0363	0.0140	0.0011	0.0141	0.0084
Deployment status	ns	ns	ns	ns	ns	ns
Location (U.S./Overseas)	ns	0.0008	ns	ns	-	ns
Region of the US/World	ns	0.0038	ns	ns	ns	0.0000
Component	-	-	-	-	-	ns

ns=not statistically significant at the 5% level in the final model.

- = not included in model.

Data Files

Two SAS files were created to document sampling and weighting for the *1996 Equal Opportunity Survey*. These files were used by DMDC in preparation of the *EOS*:

- Public Use File, and
- Confidential DMDC File.

The file prepared by RTI for the preparation of the Public Use File contains 43,113 records. Two types of respondent records are included on this file: data collected from ineligible study subjects (ineligibles), and data collected from eligible study subjects (eligibles). Both the eligibles and ineligibles are counted as respondents since the eligibility status for the study is determined. The file prepared by RTI for the preparation of the Confidential DMDC File contains the 43,113 records prepared for the Public Use File plus 33,641 records from the study nonrespondents for a total of 76,754 records. Appendix F describes the variables contained on these files and gives SAS code used to create the variables.

Appendix A

Analysis of the EOS Using SUDAAN[®]

This appendix describes the use of the SUDAAN[®] (Shah, Barnwell, & Bieler, 1996) for the analysis of data from the 1996 EOS. SUDAAN[®] is the Research Triangle Institute's (RTI) software which was developed for analyzing data from complex sample designs. Sections in this appendix discuss: the sample design features that determine the SUDAAN[®] options to use; the SUDAAN[®] design options; how SUDAAN[®] can be used for within-survey comparisons; making statistical comparisons with the results of other surveys; and the use of SUDAAN[®]'s regression procedures with these data. SUDAAN[®] uses the Taylor series linearization method for variance estimation of ratios; this method is described in Appendix E. Other software designed for the analysis of complex survey data that would also be appropriate to use is described by Cohen (1997). Refer to Cochran (1977, p. 166) for guidelines on checking the coefficient of variation of the denominator for evaluating the Taylor series variance approximation.

Sample Design Features of the EOS Survey

This section discusses design features that determine the SUDAAN[®] options to use. EOS employed a *stratified, single stage* sample design. Strata were constructed from variables described in the Sample Design section. A simple random sample of persons was selected from each of the strata. The sample was selected *without replacement*; in some of the strata the *sampling fractions* are so large that the *finite population correction factor (fpc)* which is used in the variance formula is not negligible. Most surveys use without replacement designs; but in many cases the sampling fraction is small and can be ignored (see Cochran, 1977, p. 25 for guidance on ignoring the fpc). To use the without replacement formulas, the user should include the option **DESIGN=STRWOR** on the PROC statement. EOS data could also be analyzed using the with replacement variance estimation option; the estimated variances would be expected to be larger than when the without replacement option is used.

A collapsed strata variable, formed by combining strata with fewer than 25 observations, was formed for use in variance estimation, and is appropriate to use on the SUDAAN[®] **NEST** statement. The user must also specify the population totals for each stratum in the sample design; this is done through the use of a variable on the SUDAAN[®] **TOTCNT** statement.

Because all weighted cases are used to estimate the variance structure, all weighted cases are kept on the analysis file, even cases not in the subpopulation of interest. This applies both in the general case of ineligibility and specific cases of analyses focused on a part of the population⁵.

⁵ The one exception to this rule is that theoretically all cases are not required for variance estimation when the subpopulation is defined by a stratification variable that fully crosses the design (i.e., no part of the stratification variable was collapsed in forming the strata). CSERVICE (with levels for the Army, Navy, Marine Corps, Coast Guard, and AGR/TARs) is the only stratification variable that meets this criterion. This variable is not available on public use files because it could be used when crossed with other variables to identify individuals).

Because ineligibility occurred between sample selection and mailing of the survey (e.g., persons leaving the military or persons dying), the sample included a small number of ineligibles. Sampled persons who could be identified as *ineligibles* are treated as respondents for variance calculations and appear on the file with a positive weight. Ineligibles are needed on the analysis file in order for SUDAAN® to properly calculate the variances. If the proportion of ineligibles is small, whether or not they are included generally makes little practical difference in the variance estimates. There is an eligibility indicator on the *EOS* files which takes values

ELIGFLGW = 1, survey eligible
 = 0, survey ineligible
 = ., nonrespondent

This variable is used on the **SUBPOP**N statement in SUDAAN® to cause the ineligible persons to be excluded from the estimates, but included properly for variance estimation.

Analysts may only be interested in point estimates for a specifically defined subpopulation, say members of the Army. Although the responses from members of the other Services are not required for point estimates for the Army, they are required for the variance estimates. In this example, the **SUBPOP**N statement would read:

SUBPOPN ELIGFLGW = 1 & XSVC = 1;

See the SUDAAN® manual for details on specifying more complexly defined subpopulations. This example is given here to illustrate the need to keep all weighted cases in the file and to define the subpopulation of interest on the **SUBPOP**N statement.

Design Options

The considerations just described indicate that these SUDAAN® design options should be used:

DESIGN=STRWOR;	Appears on the PROC statement
NEST VSTRAT;	A single variable appears on the NEST statement
TOTCNT NVSTRAT;	A single variable giving the population totals appears on the TOTCNT statement
SUBPOP N ELIGFLGW = 1;	Is used to define the domain of interest for the study, but keep all weighted records on the file for variance estimation (i.e., all cases where WGHT_FLG=1)
WEIGHT ANL_WT;	This is the final weight constructed for analyses

Within Survey Comparisons

Comparing Two Subgroups

For comparing one subgroup with another within a survey (e.g., non-Hispanic Blacks vs. non-Hispanic Whites, the SUDAAN® **DIFFVAR** statement in the **DESCRIPT** and **RATIO** procedures is used to obtain the estimate of the difference and the standard error of that difference. SUDAAN® 6.4 and later versions have options for computing and printing the *t*-statistic and *p*-values.

Comparing Two Analysis Variables

Using a *t*-test with the standard errors printed by SUDAAN® will not give the correct test for comparing the means of two variables from the same questionnaire because these data are measured on the same people and are correlated. SUDAAN® does not have an option that will easily allow the user to compare two analysis variables; it is necessary to work with the data to compute the statistical test. This section demonstrates two ways for using SUDAAN® to perform this type of test.

If the missing data patterns are the same for the two variables then the user can create a new variable which is the difference of the two variables being compared, and use this new variable on the SUDAAN® **VAR** statement.

Another method that is more general and allows not only the comparison of means, but also the comparison of distributions of two variables using the chi square tests in **CROSSTAB** is the trick of doubling the data file and creating a variable which is "1" for the first half of the doubled data and is "2" for the second half. At the same time, the user creates a new analysis variable which is set to the first variable to be compared in the first half of the file, and to the second variable in the second half of the file. There is also a person identification variable (**DMDC_ID**) on the file. Then SUDAAN® is run with the **WOR** option and two variables (**VSTRAT** and **DMDC_ID**) on the **NEST** statement.

These two techniques are best illustrated with an example. Suppose **DESCRIPT** has been used to get the mean of questionnaire items Q10 and Q20. If Q10 and Q20 are 0-1 variables then SUDAAN® would produce estimates of the proportions. A SUDAAN® program for obtaining estimated means and standard errors for the two variables individually consists of the following statements:

```
PROC DESCRIPT DESIGN=STRWOR DATA=EOSDATA;  
SUBPOPN ELIGFLGW=1;  
NEST VSTRAT;  
TOTCNT NVSTRAT;  
WEIGHT ANL_WT;  
VAR Q10 Q20;  
PRINT MEAN SEMEAN;  
TITLE "Means for Variables Q10 and Q20";
```

If the missing data patterns are the same for Q10 and Q20, that is, if there is a nonmissing value for Q10 and also Q20, or both are missing simultaneously, and they are continuous (or 0-1 variables) then one method is to compute the difference, $Q10 - Q20$, for each person in the data file and rerun SUDAAN® using this difference on the VAR statement, as follows:

```
DATA EOS; SET IN.EOSDATA;  
DIFF1020=Q10 - Q20;  
PROC DESCRIPT DATA=EOSDATA DESIGN=STRWOR FILETYPE=SAS;  
SUBPOPN ELIGFLGW=1;  
NEST VSTRAT;  
TOTCNT NVSTRAT;  
WEIGHT ANL_WT;  
VAR DIFF1020;  
PRINT MEAN SEMEAN T_MEAN P_MEAN;  
TITLE "Differences between Q10 and Q20";
```

The difference of the means and the sample sizes printed should correspond to the manually calculated difference of the means and the sample sizes from the previous example.

The following example demonstrates the more general method of doubling the data file.

```
DATA DOUBLE; SET EOSDATA;
/* first variable to be compared */
NEWVAR=Q10;
GROUP=1;
OUTPUT;
/* second variable to be compared */
NEWVAR=Q20;
GROUP=2;
OUTPUT;
PROC SORT DATA=DOUBLE; BY VSTRAT DMDC_ID;
PROC DESCRIPT DATA=DOUBLE DESIGN=WOR;
SUBPOPN ELIGFLGW=1;
NEST VSTRAT DMDC_ID;
TOTCNT NVSTRAT _MINUS1_;
WEIGHT ANL_WT;
VAR NEWVAR;
SUBGROUP _ONE_ GROUP;
LEVELS 1 2;
TABLES _ONE_;
DIFFVAR GROUP=(1,2);
PRINT MEAN SEMEAN T_MEAN P_MEAN;
```

Comparing Estimates from Different Surveys

A *t*-statistic for independent samples can be used to compare an estimate obtained from one survey with an estimate obtained from an independently selected sample in another survey. For example, the samples for DMDC's 1995 *Sexual Harassment Survey (SHS)* and the 1996 *EOS* are independent. Each of the surveys contains a questionnaire item where the respondents report level of satisfaction with their jobs; this is item Q70 on the *SHS* and item Q26H on the *EOS*.

To compare the proportions of persons who report that they are "very satisfied with their job as a whole," first use SUDAAN to compute the proportions and standard errors for each of the surveys separately. For *EOS* this can be done by first defining a variable which takes the value 1 if the respondent reported "very satisfied" to item Q26H, and the value 0 if the respondent reported any other nonmissing response. Next, use this 0-1 variable on the **VAR** statement in the **DESCRIPT** procedure (with the design options described earlier in this appendix) to obtain the estimated proportion and standard error from the *EOS*; denote the estimated proportion and standard error by p_{EOS} and se_{EOS} .

Similarly, compute the corresponding estimates from the *SHS* using the variable Q70, following the procedures given in the methodology report for that survey (Mason, Wheelless, Kavee, George, Elig, & Riemer, 1996); denote the estimated proportion and standard error by p_{SHS} and se_{SHS} .

To compare the proportions p_{SHS} and p_{EOS} , the following formula is used for computing the standard error of the difference:

$$se_{SHS-EOS} = \sqrt{se_{SHS}^2 + se_{EOS}^2}$$

and this formula to compute the *t*-statistic for testing the difference:

$$t = \frac{p_{SHS} - p_{EOS}}{se_{SHS-EOS}}$$

Regression Analysis

Linear and logistic regression models for data from this stratified, unequally weighted sample design can be fitted using the SUDAAN[®] procedures **REGRESS** and **LOGISTIC**. The **NEST**, **WEIGHT**, **DESIGN=**, and **TOTCNT** statements and options are identical to those used in the descriptive procedures.

REGRESS produces design-weighted least squares estimates of the model parameters and their variance-covariance matrix for linear regression models. **LOGISTIC** provides modeling capabilities for dichotomous or ordinal outcome variables using maximum likelihood techniques.

These procedures compute tests of the null hypothesis that individual regression coefficients in the beta vector are equal to zero. They compute tests for overall model significance, model minus intercept, as well as main effects and interaction effects.

⁸ The precision constraints that determine the allocation solutions are identified by those final Lagrange multipliers that are most closely equal in value to the initial values described in the Sample Design section of this report, giving ratios close to one. Values in this column are the percentages that the final values are of the initial values. Constraints that are satisfied coincidentally to others have final Lagrange multiplier values of zero.

⁹ The expected precision is calculated using the allocation solutions reported in Table B-4 and is the half width of a 95% confidence interval.

¹⁰ Design effects are the ratios of the actual variances to those that would be obtained using a simple random sampling design with the same number of observations.

¹¹ response rate = $\frac{\text{eligible respondents} + \text{known ineligible}}{\text{total sample}}$. The interval estimate gives lower and upper endpoints of

a 95% confidence interval for the response rate. The response rates for the "Enlisted unknown" and "Officer unknown" categories were suppressed because of small sample sizes.

Table B-15.

Response Rates and Percentage Distribution of EOS Respondents, Nonrespondents, and Total Population for the Total Military, by Demographic Characteristics

Characteristics	Response Rate	Percentage Distribution

Appendix C

Taylor Series Linearizations For Two Variable Functions

The Taylor series expansion for a function of two variables $f(x, y)$ about the values $x = a$ and $y = b$ is given by,

$$\begin{aligned}
 f(x, y) &= f(a, b) + \left((x-a) \frac{\partial f(x, y)}{\partial x} \Big|_{x=a} + (y-b) \frac{\partial f(x, y)}{\partial y} \Big|_{y=b} \right) \\
 &\quad + \frac{1}{2!} \left((x-a)^2 \frac{\partial^2 f(x, y)}{\partial x^2} \Big|_{x=a} + (y-b)^2 \frac{\partial^2 f(x, y)}{\partial y^2} \Big|_{y=b} + (x-a)(y-b) \frac{\partial^2 f(x, y)}{\partial x \partial y} \Big|_{x=a, y=b} \right) \\
 &\quad + \dots \\
 &\approx f(x, y) = f(a, b) + \left((x-a) \frac{\partial f(x, y)}{\partial x} \Big|_{x=a} + (y-b) \frac{\partial f(x, y)}{\partial y} \Big|_{y=b} \right).
 \end{aligned}$$

The variance of $f(x, y)$ is,

$$\begin{aligned}
 Var\{f(x, y)\} &= E\{f(x, y)^2\} - (E\{f(x, y)\})^2 \\
 &\approx E\left\{ \left(f(a, b) + \left((x-a) \frac{\partial f(x, y)}{\partial x} \Big|_{x=a} + (y-b) \frac{\partial f(x, y)}{\partial y} \Big|_{y=b} \right) \right)^2 \right\} \\
 &\quad - \left(E\left\{ f(a, b) + \left((x-a) \frac{\partial f(x, y)}{\partial x} \Big|_{x=a} + (y-b) \frac{\partial f(x, y)}{\partial y} \Big|_{y=b} \right) \right\} \right)^2.
 \end{aligned}$$

Define $E\{x\} = a$ and $E\{y\} = b$. Then the above approximate variance becomes,

$$Var\{f(x, y)\} \approx E\left\{ (x-a)^2 \left(\frac{\partial f(x, y)}{\partial x} \Big|_{x=a} \right)^2 \right\} + E\left\{ (y-b)^2 \left(\frac{\partial f(x, y)}{\partial y} \Big|_{y=b} \right)^2 \right\}$$

$$\begin{aligned}
& +2E\left\{(x-a)(y-b)\left(\frac{\partial f(x,y)}{\partial x}\right)\bigg|_{x=a}\left(\frac{\partial f(x,y)}{\partial y}\right)\bigg|_{y=b}\right\} \\
& = Var\left\{x\right\}\left(\frac{\partial f(x,y)}{\partial x}\right)\bigg|_{x=a}^2 + Var\left\{y\right\}\left(\frac{\partial f(x,y)}{\partial y}\right)\bigg|_{y=b}^2 \\
& \quad +2Cov\left\{x,y\right\}\left(\frac{\partial f(x,y)}{\partial x}\right)\bigg|_{x=a}\left(\frac{\partial f(x,y)}{\partial y}\right)\bigg|_{y=b}.
\end{aligned}$$

For example, if $f(x,y) = \frac{x}{y}$ as in a ratio estimate, then the Taylor series approximation is given by,

$$Var\left\{f(x,y)\right\} \approx \frac{1}{b^2}\left(Var\{x\} + \left(\frac{a}{b}\right)^2 Var\{y\} - 2\frac{a}{b}Cov\{x,y\}\right).$$

The same variance approximation can be obtained by defining the linearized variable, $z = x - \frac{a}{b}y$. The variance of z is,

$$\begin{aligned}
Var\{z\} & = E\left\{\left(x - \frac{a}{b}y\right) - E\left\{x - \frac{a}{b}y\right\}\right\}^2 \\
& = E\left\{\left(x - a\right) - \frac{a}{b}(y - b)\right\}^2 \\
& = Var\{x\} + \left(\frac{a}{b}\right)^2 Var\{y\} - 2\frac{a}{b}Cov\{x,y\}.
\end{aligned}$$

Note that this variance is b^2 times the Taylor series approximation given above. That is

$$Var\left\{\frac{x}{y}\right\} = \frac{1}{b^2}Var\{z\}.$$

Appendix D

Derivation of Initial Lagrange Multiplier Values for a Stratified Random Sampling Design

Derivation

For a single variance constraint, given a stratified random sampling design, interest lies in minimizing the objective function

$$o(n_h, \lambda) = \sum_h n_h \bar{C}_h + \lambda \sum_h \left(\frac{N_h}{N} \right)^2 \frac{P_h(1 - P_h)}{n_h} - K,$$

where the h -subscript denotes the design strata and,

n_h = the unknown sample size to be selected from the h -th stratum,

λ = a generalized Lagrange multiplier,

N_h / N = the relative size of the h -th stratum in the population,

$P_h(1 - P_h)$ = the population variance of a defined proportion in the h -th stratum,

K = the variance constraint placed on the sample estimate of P_h .

The objective function as written above ignores the finite population correction (as though the sample were selected with replacement).

Taking derivatives of the objective function with respect to the unknown sample sizes n_h yields equations of the form

$$\frac{\partial(o(n_h, \lambda))}{\partial(n_h)} = \bar{C}_h + \lambda \frac{\left(\frac{N_h}{N} \right)^2 P_h(1 - P_h)}{-n_h^2}.$$

Setting these equations to zero and solving for n_h yields the solutions,

$$n_h = \sqrt{\lambda} \frac{N_h}{N} \sqrt{P_h(1 - P_h)} / \sqrt{\bar{C}_h}. \quad (D-1)$$

For the one-constraint case, the allocation solutions can also be obtained explicitly. Cochran (1963) on pages 95-96 solves for the values

$$\frac{n_h}{n} = \frac{\frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h}}{\sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h}}$$

and

$$n = \frac{\left(\sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} \sqrt{C_h} \right) \sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h}}{K},$$

(again ignoring the finite population effect). Combining these two results gives the explicit solution

$$n_h = \frac{\frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h} \sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} \sqrt{C_h}}{K} \quad (\text{D-2})$$

Then from Equations (1) and (2) we have

$$\sqrt{\lambda} \frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h} = \frac{\frac{N_h}{N} \sqrt{P_h(1-P_h)} / \sqrt{C_h} \sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} \sqrt{C_h}}{K}$$

from which

$$\sqrt{\lambda} = \frac{\sum_h \frac{N_h}{N} \sqrt{P_h(1-P_h)} \sqrt{C_h}}{K} \quad (\text{D-3})$$

Some Observations

The initial Lagrange multiplier value (Equation (D-3)) receives a contribution from each stratum that has a value $P_h > 0$. The largest strata, those with a P_h -value approaching 0.50 and those with the largest per unit average cost, contribute more to the λ -value than do small strata with P_h -values approaching zero or one and small per unit costs. However, the stratum sizes and per unit costs do not depend on the domain, such that differences among initial λ -values depend only on the values P_h and K .

Thus, the largest λ -values starting out will belong to those domains for which P_h approaches 0.5 and for which K is smallest. Note that K is itself a variance having a value less than one for binomial proportions for any reasonable constraint. Because K appears in the denominator, the smaller values will produce the larger λ -values. So, in summary, the largest

initial Lagrange multipliers will be those that correspond to the largest population proportions (up to a maximum of 0.50) if these proportions also have the more restrictive constraints imposed on them.

Appendix E

Estimation Procedures

Procedures for estimating population totals, means, proportions, and regression relations and their associated variances are presented in this section. The estimation procedures are derived from the sampling design described in the Sampling Design section of this report. Modifications made to the design-based estimation procedures to compensate for missing data are presented in a subsequent section. The procedures described in this appendix are implemented in the SUDAAN® software package (Shah, et al., 1996). Appendix A of this report gives instructions for the use of SUDAAN® with the EOS data.

The sampling design described earlier provides unbiased estimates of parameters estimated by linear statistics and their associated variances. Given the design, examples of parameters estimated by linear statistics include population totals, means and proportions, and some subpopulation or domain means and proportions. Other subpopulation or domain means and proportions are estimated by non-linear statistics. The distinction is based on whether the denominators of the domain means and proportions are known, or are unknown and need to be estimated from the sample.

For example, consider the proportion of eligible, non-Hispanic Blacks who report having experienced one or more incidents of racial/ethnic harassment or discrimination. If all persons were eligible for the survey, the denominator (the total number of non-Hispanic Blacks in the population) would be a known quantity. The numerator, the total number of non-Hispanic Blacks who report having experienced racial/ethnic harassment or discrimination, is estimated from the sample. The proportion is therefore estimated by a linear statistic. In contrast, consider a similar proportion defined for some domain of non-Hispanic Blacks identified by individual responses to one or more questionnaire items, say the proportion of non-Hispanic Blacks who experienced racial/ethnic harassment or discrimination who did not report it to authorities. In this case the denominator total, the number of non-Hispanic Blacks in the population who experienced racial/ethnic harassment or discrimination, is unknown and must be estimated from the sample along with the numerator. The estimator as a result is a non-linear statistic (i.e., a ratio of random variables).

In the case of regression relations, both the *dependent* or *criterion* variables and the *independent* or *explanatory* variables are obtained from the sample. Thus, in general, regression coefficients in a finite population context are estimated by non-linear statistics. An example of a regression relation might be the association between the average number of reported incidents and the age and rank of the individuals.

The design-based estimation procedures are described in the following subsections with separate subsections for linear, ratio, and regression estimates. Each subsection begins with the definition of the relevant parameters. The definitions are followed by a description of the procedure for estimating the parameters and their sampling variances. Notation is developed as needed in the context of the presentation.

Linear Statistics and Associated Variances

Definitions

Units in the population (i.e., persons in the active-duty military) are identified by the subscript $g = 1, 2, \dots, N$, the population being comprised of a total of N units. Response variable values are typically questionnaire items or items of information about individuals available in the source information used to construct the sampling frame; response variable values associated with the g -th unit in the population are denoted using $\{x_g, y_g, \dots, z_g\}$.

The population total of the response variables y_g is defined as the quantity

$$T_y = \sum_{g=1}^N y_g ,$$

and the population mean or average as the quantity

$$A_y = \frac{1}{N} \sum_{g=1}^N y_g .$$

Sample estimates of these quantities are denoted by \hat{T}_y and \hat{A}_y .

Domain totals and domain means are defined by the quantities,

$$T_{d,y} = \sum_{g=1}^N \delta_{d,g} y_g ,$$

$$A_{d,y} = \frac{T_{d,y}}{N_d} , \tag{E-1}$$

where the subscript, d , denotes a particular domain of interest, and,

$$\begin{aligned} \delta_{d,g} &= 1, \text{ if the } g\text{-th unit in the population belongs to the } d\text{-th domain,} \\ &= 0, \text{ otherwise.} \end{aligned}$$

For example, the d -subscript might identify non-Hispanic Blacks, implying $\delta_{d,g} = 1$ if the person identified by the g -subscript is non-Hispanic Black and zero otherwise. If the response variable value y_g is the number of incidents reported by the g -th individual, then the sum of the products $\delta_{d,g} \times y_g$ is the total number of incidents reported by non-Hispanic Blacks.

In particular, if $y_g = 1$ for all values of the g -subscript, then the sum of the products $\delta_{d,g} \times y_g$ is the number of individuals that belong to the d -th domain, denoted by N_d . Continuing the example in the previous paragraph, N_d is the total number of non-Hispanic Blacks in the military.

Also y_g may be categorical, implying $y_g = 1$ if the g -th unit in the population possesses some attribute of interest, and $y_g = 0$ otherwise. In this case, Equation E-1 defines a proportion which can be denoted using

$$P_{d,y} = \frac{N_{d,y}}{N_d}$$

to distinguish it from a domain mean $A_{d,y}$. Continuing the example, define $y_g = 1$ if the g -th unit in the population reports at least one incident of racial/ethnic harassment or discrimination. Then the sum of the products $\delta_{d,g} \times y_g$ is the number of non-Hispanic Blacks who report at least one incident, providing the numerator of the proportion, $P_{d,y}$.

Estimation

In what follows, strata are denoted by the subscript $h = 1, 2, \dots, H$, where $H = 255$.

An estimated total is computed as the sum of the estimated stratum-level totals. Notationally,

$$\hat{T}_{d,y} = \sum_h \hat{T}_{d,y,h} \quad (E-2)$$

For this survey, sample individuals from the same stratum were selected with equal probability, implying that the stratum-level estimates are the quantities

$$\hat{T}_{d,y,h} = \frac{N_h}{n_h} \sum_{i=1}^{n_h} \delta_{d,h,i} y_{h,i} = \frac{N_h}{n_h} t_{d,y,h} \quad (E-3)$$

In this expression, the individuals selected into the sample are identified using the subscript $i = 1, 2, \dots, n_h$, where n_h is the sample size for the h -th stratum. N_h is the total number of individuals classified into the h -th stratum (i.e., the stratum size). The quotients $N_h \div n_h$ are the sampling weights for individuals classified into the h -th stratum. Finally, the sample total,

$$t_{d,y,h} = \sum_{i=1}^{n_h} \delta_{d,h,i} y_{h,i} ,$$

is the sum of the response variable values over the sampled individuals in the stratum who are members of the domain. The n_h and N_h values are listed in Table B-6 in Appendix B.

Because the samples were selected independently from each stratum, the stratum-level variances are additive. Hence, from Equation E-2,

$$Var\{\hat{T}_{d,y}\} = Var\left\{\sum_h \hat{T}_{d,y,h}\right\} = \sum_h Var\{\hat{T}_{d,y,h}\}.$$

Because the samples were selected with equal probability and without replacement given the stratum, we have for the estimated variance of the estimated stratum totals given in Equation E-3,

$$\hat{Var}\{\hat{T}_{d,y,h}\} = \hat{Var}\left\{\frac{N_h}{n_h} \sum_{i=1}^{n_h} \delta_{d,h,i} y_{h,i}\right\} = \frac{N_h(N_h - n_h)}{n_h(n_h - 1)} \left(\sum_{i=1}^{n_h} \delta_{d,h,i} y_{h,i}^2 - \frac{t_{d,y,h}^2}{n_h} \right). \quad (E-4)$$

The derivations of the above equations can be found in most sampling texts. Equation E-4 can be found in Cochran (1977), Section 5A.14, page 143, except that he uses a j -subscript to denote a domain of interest and the symbol, $y_{h,i,j}$, in place of the product, $\delta_{d,h,i} \times y_{h,i}$.

Given that the denominator quantity is known, then an estimated domain mean is simply

$$\hat{A}_{d,y} = \frac{1}{N_d} \hat{T}_{d,y},$$

with the associated variance estimate,

$$\hat{Var}\{\hat{A}_{d,y}\} = \left(\frac{1}{N_d} \right)^2 \hat{Var}\{\hat{T}_{d,y}\}.$$

An alternate form of Equation E-4 simplifies the presentation of the variance estimates for non-linear statistics presented in the next two subsections. Equation E-4 uses the person-level quantities $\delta_{d,h,i} \times y_{h,i}$ to compute the variance estimate. Alternately, the variances can be computed using the person-level quantities,

$$\hat{T}_{d,y,h,i} = \frac{N_h}{n_h} \delta_{d,h,i} y_{h,i}. \quad (E-5)$$

These quantities can be thought of as the person-level contributions to the estimated population total for the h -th stratum which can be equivalently rewritten as,

$$\hat{T}_{d,y,h} = \sum_{i=1}^{n_h} \hat{T}_{d,y,h,i} \quad (E-6)$$

(see Equation E-3).

The alternate form of the stratum-level variance replaces the term in parentheses in Equation E-4 with the sum of the squared differences between the person-level contributions in Equation E-5 and their average (i.e., the estimated stratum total) in Equation E-6. Note that the

sum in question is $(N_h \div n_h)^2$ times the term it replaces. Hence, the alternate form of the variance is,

$$\hat{Var}\{\hat{T}_{d,y,h}\} = \left(\frac{N_h - n_h}{N_h}\right) \left(\frac{n_h}{n_h - 1}\right) \sum_{i=1}^{n_h} \left(\hat{T}_{d,y,h,i} - \hat{T}_{d,y,h}\right)^2. \quad (E-7)$$

Equation E-7 rather than Equation E-4 is used in the following discussion.

Ratio Estimates and Associated Variances

Definitions

If both the numerator and denominator quantities are estimates, that is, if

$$\hat{A}_{d,y} = \frac{\hat{T}_{d,y}}{\hat{N}_d}, \quad (E-8)$$

then, because both the numerator and denominator are random variables, the estimator is a non-linear statistic. Non-linear statistics in general are not unbiased and variance estimates are not available in closed form (i.e., they can only be approximated by success approximations).

The bias potential depends on the variability associated with the denominator total. If a large number of observations is available for estimating the denominator, the bias potential can usually be safely ignored. Cochran (1977, page 166) suggests that the bias properties of a combined ratio estimate relative to their standard errors are negligible provided that the coefficient of variation of the denominator per unit mean¹² is less than 10 percent. However, for narrowly defined domains with samples disproportionately allocated to a large number of strata, the standard error of the denominator can be quite large. In selecting ratio quantities for reporting purposes, the variance of the denominator estimate should be routinely assessed, particularly when the denominator total is estimated using information from strata that receive a relatively small sample allocation. Under most circumstances a denominator degrees of freedom of 30 is considered sufficiently large.

Variance approximations for non-linear statistics are typically based on Taylor series linearizations or on re-sampling (pseudo-randomization) procedures such as those based on random groups. Wolter (1985) describes in detail most, if not all, of the procedures commonly used. We recommend using first order Taylor series linearizations as described in Appendix A (see also Wolter, 1985, Chapter 6).

¹² Note that Equation E-8 can be equivalently written as

$$\hat{A}_{d,y} = \frac{\hat{T}_{d,y} / N}{\hat{N}_d / N}.$$

Cochran's result is stated in terms of the standard error of \hat{N}_d / N and the coefficient of variation of the corresponding population parameter.

Estimation

The unknown denominator total N_d is estimated using the equations for population totals described in the previous section by setting $y_{h,i} = 1$ for all values of the h - and i -subscripts. That is

$$\hat{N}_d = \sum_h \hat{N}_{d,h} = \sum_h \frac{N_h}{n_h} \sum_{i=1}^{n_h} \delta_{d,h,i} = \sum_h \frac{N_h}{n_h} n_{d,h}, \quad (\text{E-9})$$

is computed and used in Equation E-8. Equation E-9 can be equivalently written as

$$\hat{N}_d = \sum_h \sum_{i=1}^{n_h} \frac{N_h}{n_h} \delta_{d,h,i},$$

which provides a more direct interpretation of the estimate \hat{N}_d as the sum of the sampling weights over all of the individuals that belong to the domain. For example, the sum of the sampling weights of persons who report that they plan to remain in the Service is the sample estimate of the total persons planning this action.

Equation E-9 itself defines a linear statistic. The non-linearity problem arises in association with using the estimate \hat{N}_d in the denominator of the estimated population mean $\hat{A}_{d,y}$ as described in Equation E-8. The approximate variance of the estimate given in Equation E-8 is obtained by first computing the linearized variables¹³,

$$z_{d,h,i} = \delta_{d,h,i} (y_{h,i} - \hat{A}_{d,y})$$

and using these in place of the products $\delta_{d,h,i} \times y_{h,i}$ in Equation E-5 to compute the variances $\hat{Var}\{\hat{T}_{d,z,h}\}$. That is, first compute the variances,

$$\hat{Var}\{\hat{T}_{d,z,h}\} = \left(\frac{N_h - n_h}{N_h} \right) \left(\frac{n_h}{n_h - 1} \right) \sum_{i=1}^{n_h} \left(\hat{T}_{d,z,h,i} - \hat{T}_{d,z,h} \right)^2, \quad (\text{E-10})$$

where,

$$\hat{T}_{d,z,h,i} = \frac{N_h}{n_h} z_{d,h,i},$$

$$\hat{T}_{d,z,h} = \frac{1}{n_h} \sum_{i=1}^{n_h} \hat{T}_{d,z,h,i}.$$

¹³ The development of the linearized variable is described in Appendix C.

Equation E-10 is not, however, the variance sought (which is the variance of the domain mean), rather an intermediate step in the calculations. To complete the calculation the variances of the linearized variables are summed over the strata and divided by the square of the estimated denominator quantity. Notationally,

$$\hat{Var}\{\hat{A}_{d,y}\} \approx \left(\frac{1}{\hat{N}_d}\right)^2 \sum_h \hat{Var}\{\hat{T}_{d,z,h}\}. \quad (E-11)$$

Regression Relations

Definitions

Estimates of regression coefficients and their associated variance-covariance matrix are obtained using a multivariate extension of the estimators described in the previous section. In a finite population context, a regression analysis assesses the ability of p -element vectors of response variable values, denoted by \underline{x}_g , to explain the values of another set of response variable values, denoted by y_g . In the notation used here, an underlined lower case letter (e.g., \underline{x}_g) denotes a vector, and a lower case letter with no underline (e.g., y_g) denotes a scalar. As previously, the g -subscript denotes individuals in the population. There is no inherent difference between the response variable values that are chosen to comprise the vectors of explanatory variables, \underline{x}_g , and those designated as the criterion variables, y_g . Both arise coincidentally in association with the g -th individual in the population. The distinction arises merely in the context of a given analysis.

For example, the association between incidents of unwanted racial/ethnic attention and other factors can be expressed using a regression relation. The survey data provide observations of the number of incidents, y_g , and the other factors \underline{x}_g for those values of the g -subscript selected into the sample. Both the y_g and the \underline{x}_g values are random variables subject to the same sources of variation. Hence the problem of estimating the regression coefficients and their associated variance-covariance matrix is a non-linear problem. The situation is contrasted with that occurring in experimental situations where the \underline{x}_g values are typically fixed by the investigator and the estimated regression coefficients are linear statistics.

In a finite population context, regression coefficients can be defined as follows. Consider the function of observation variables defined by

$$\theta_g = y_g - \sum_{l=1}^p x_{g,l} \beta_l, \quad g = 1, 2, \dots, N.$$

The population mean and variance of the function θ_g are, by definition, the quantities

$$A_\theta = \frac{1}{N} \sum_{g=1}^N \theta_g = A_y - \sum_{l=1}^p A_{x,l} \beta_l,$$

$$V_{\theta} = \frac{1}{N} \sum_{g=1}^N (\theta_g - A_{\theta})^2 = \frac{1}{N} \sum_{g=1}^N \left(\left(y_g - \sum_{l=1}^p x_{g,l} \beta_l \right) - \left(A_y - \sum_{l=1}^p A_{x_l} \beta_l \right) \right)^2. \quad (E-12)$$

Equation E-12 holds for any choice of the regression coefficients β_l . Reasonable choices are those values of β_l that minimize the variance V_{θ} . With this choice, the regression coefficients are defined at population levels so as to minimize the ordinary least squares criterion. That is,

$$\underline{\beta} = V_{\underline{x}'\underline{x}}^{-1} V_{\underline{x}'y}. \quad (E-13)$$

In this expression, $\underline{\beta}$ is a column vector with p elements. $V_{\underline{x}'\underline{x}}^{-1}$ is the inverse of a $p \times p$ square matrix with diagonal elements

$$V_{x_l x_l} = \frac{1}{N} \sum_{g=1}^N (x_{g,l} - A_{x_l})^2,$$

which are the population variances of the explanatory variables, and off-diagonal elements

$$V_{x_l x_{l'}} = \frac{1}{N} \sum_{g=1}^N (x_{g,l} - A_{x_l})(x_{g,l'} - A_{x_{l'}}), \quad l \neq l',$$

which are the explanatory variable covariances. $V_{\underline{x}'y}$ is a p -element column vector containing the covariances between the criterion variable and the explanatory variables. That is,

$$V_{x_l y} = \frac{1}{N} \sum_{g=1}^N (x_{g,l} - A_{x_l})(y_g - A_y).$$

Sarndal, Swensson, & Wretman (1992, Section 13.2, page 486) follow a similar development in defining regression coefficients in the context of finite populations.

Estimation

As in the example in the previous section dealing with ratio estimates and associated variances, the variance-covariance matrix $V_{\underline{x}'\underline{x}}^{-1}$ forms a multivariate denominator total to be estimated using the sample data. The numerator total is the vector quantity $V_{\underline{x}'y}$. First, the unit-level quantities $\underline{x}'_g \underline{x}_g$ and $\underline{x}'_g y_g$ are computed for the units in the sample. Then these are weighted and added over the strata. Domain specific regressions are computed by applying the domain indicator variables as in the previous subsections. Notationally, the estimate is

$$\hat{V}_{\underline{x}'\underline{x}} = \sum_h \frac{N_h}{n_h} \sum_{i=1}^{n_h} \delta_{d,h,i} \underline{x}'_{h,i} \underline{x}_{h,i}.$$

The inverse of the matrix, $\hat{V}_{x'x}^{-1}$, is computed using standard procedures. Similarly, the numerator quantity is estimated by

$$\hat{V}_{x'y} = \sum_h \frac{N_h}{n_h} \sum_{i=1}^{n_h} \delta_{d,h,i} x'_{h,i} y_{h,i}.$$

The estimated regression coefficients are then computed by pre-multiplying the numerator vector by the inverse matrix.

The Taylor series linearized variables¹⁴ used to compute the variance-covariance matrix of the regression coefficients, are defined by the p -element column vectors,

$$z_{d,h,i} = \delta_{d,h,i} x'_{h,i} (y_{h,i} - \underline{x}_{h,i} \underline{\beta}).$$

Each observation contributes the amount

$$\hat{T}_{d,z,h,i} = \frac{N_h}{n_h} z_{d,h,i}$$

to the estimated total for the h -th stratum which, as in Equation E-6, can be written as the average of the individual contributions. That is,

$$\hat{T}_{d,z,h} = \frac{1}{n_h} \sum_{i=1}^{n_h} \hat{T}_{d,z,h,i}.$$

To form the variance-covariance matrix of the (p -element vector) stratum totals, take the difference between the observation-level contributions to the stratum totals and the stratum total, and then post-multiply by its transpose. Then sum the resulting matrices over the set of observations. That is,

$$\hat{Var}\{\hat{T}_{d,z,h}\} = \left(\frac{N_h - n_h}{N_h} \right) \left(\frac{n_h}{n_h - 1} \right) \sum_{i=1}^{n_h} \left[\hat{T}_{d,z,h,i} - \hat{T}_{d,z,h} \right] \left[\hat{T}_{d,z,h,i} - \hat{T}_{d,z,h} \right]' \quad (\text{E-14})$$

Equation E-14 replaces Equation E-10. As is the case with Equation E-10, Equation E-14 is an intermediate result. The variance-covariance matrix of the regression coefficients is computed by summing the matrices in Equation E-14 over the design strata and pre- and post-multiplying the sum by the inverse matrix $\hat{V}_{x'x}^{-1}$. That is,

$$\hat{Var}\{\hat{\underline{\beta}}\} = \hat{V}_{x'x}^{-1} \sum_h \hat{Var}\{\hat{T}_{d,z,h}\} \hat{V}_{x'x}^{-1}.$$

¹⁴ The linearized variable in the regression context is a multivariate extension of the two-variable case presented in Appendix C.

Reference is made to Sarndal et al. (1992), Section 5.10.2, pages 192 through 197 for a similar development. Sarndal and colleagues credit Folsom (1974) as being "... among the first to present results similar ..." to these.

Appendix F

Variables Contained on the Sampling and Weighting Files for the 1996 EOS

This appendix provides a description of the variables contained in files provided to DMDC to document the sampling and weighting. This appendix also gives the SAS code used for creating variables on these files.

Detailed information is first provided for a set of key variables for respondents. Two types of respondent records were included on this file, data collected from ineligible study subjects (ineligibles) and data collected from eligible study subjects (eligibles). Both the eligibles and ineligibles are categorized as respondents since the eligibility status for the study was determined. Records for the study nonrespondents are also captured on this file. Less detailed information is then provided for the full set of variables provided to DMDC.

Key Variables

The variable information is displayed using the following format:

<i>Variable:</i>	variable name
<i>Length:</i>	size of the variable
<i>Label:</i>	variable label
<i>Values:</i>	values of the variable
<i>Description:</i>	description of the variable

The variable name (*Variable*) is the name of the variable on the data set. The size of the variable (*Length*) includes the variable length and the type of variable, such as numeric or alphanumeric. Alphanumeric variables can be identified by an “A” before the variable length. The variable label (*Label*) is an expanded version of the 40 character variable label contained on the SAS data set. The section containing the values of the variable (*Values*) includes either a frequency distribution for the categorical variables or a range of values for the continuous variables. Finally, the description of the variable (*Description*) contains information such as the origin of the variable.

Variable: ANL_WT

Length: 8

Label: Analysis Weight

Values: ANL_WT is a continuous variable with the following distribution:

Maximum 579.45

Median 11.06

Minimum 1.06

Description: Sampling weights are calculated as the inverse probability of selection for each sample member. Adjustments are applied to the sampling weights to account for the study nonrespondents. Post-stratification adjustments are further applied to the weights to create the final analysis weights (ANL_WT). By summing the sampling weights for a particular domain, such as Males, an estimate of the total number of Males is calculated. Due to subject nonresponse and fluctuations in the weights, this estimate of the total differed from the total calculated from the sampling frame. The post-stratification adjustments scale the sampling weights so that the sum closely matches the sampling frame total.

See the Missing Data Compensation procedures section and Appendix E for recommended uses of the variable during analysis.

Variable: DMDC_ID

Length: 4

Label: Unique Subject Identification Number

Values: DMDC_ID is a continuous variable with the following distribution:

Maximum 76751

Median 40349

Minimum 00004

Description: Unique numeric identifier used to distinguish responses from one sample member from those responses from another sample member.

Variable: ELIGFLGW

Length: 3

Label: Eligibility Indicator

Values: ELIGFLGW is a categorical variable with the following distribution:

<u>Levels</u>	<u>Frequency</u>	<u>Percent</u>
0 = Ineligible Subjects.....	3,258	7.6%
1 = Eligible Subjects.....	39,855	92.4%
	=====	
	43,113	

Description: Sample members were classified as eligible or ineligible based on information such as administrative records and self-report records (see INELCODE discussion). Ineligible subjects are included on the data set for analysis purposes because they are representative of other ineligible subjects who did not respond. The population totals used for post-stratification adjustments also contained ineligible (see ANL_WT discussion). During analyses using the design-specific package SUDAAN, eligible subjects should be identified with the *SUBPOPN* statement. However, the records for the ineligible respondents should be eliminated prior to analyses using other statistical packages such as SAS.

See the Missing Data Compensation section and Appendix E for recommended uses of the variable during analysis.

Variable: INELCODE

Length: 3

Label: Ineligibility Status Code

Values: INELCODE is a categorical variable with the following distribution:

<u>Levels</u>	<u>Frequency</u>	<u>Percent</u>
1 = Ineligible Based On Administrative Records.....	3,075	7.1%
2 = Self-Report Ineligible.....	183	0.4%
3 = Eligible.....	39,855	92.4%
	=====	
	43,113	

Description: Sample members were classified as eligible or ineligible based on information such as administrative records and self-report records. This information was used to create an eligibility flag (see ELIGFLGW discussion). Ineligible subjects are included on the data set for analysis purposes because they are representative of other ineligible subjects who did not respond. The population totals used for post-stratification adjustments also contained ineligibles (see ANL_WT discussion). During analyses using the design-specific package SUDAAN, eligible subjects should be identified with the *SUBPOPN* statement. However, the records for the ineligible respondents should be eliminated prior to analyses using other statistical packages such as SAS.

See Appendix E for recommended uses of the variable during analysis.

Variable: NVSTRAT

Length: 4

Label: Frame Count Within Variance Stratum

Values: NVSTRAT is a continuous variable with the following distribution:

Maximum 85,127

Median 2,536

Mirimum 26

Description: A stratified random sampling design was used for the 1996 EOS survey. The sampling frame was stratified for each form by service, region, Paygrade groupings, and race/ethnicity groupings. Optimum allocation techniques were used to distribute the sample across the strata. Variance estimation requires at least two analysis records within each sampling stratum. Precision of the estimates improve as the average number of analysis records within the strata increases. Since nonresponse causes a decrease in the number of records, several strata were collapsed. Strata were combined based on the stratum variables and the response pattern within the strata. Thus weighting class strata (VSTRAT) were formed by collapsing the sampling strata to obtain a minimum sample size of 25 respondents. Sampling frame counts were calculated within the weighting class strata for analysis purposes (NVSTRAT).

See Appendix E for recommended uses of the variable during analysis.

Variable: REGION3

Length: 3

Label: Location

Values: REGION3 is a categorical variable with the following distribution:

<u>Levels</u>	<u>Frequency</u>	<u>Percent</u>
1 = United States, Northeast.....	1,899	4.4%
2 = United States, North Central.....	2,369	5.5%
3 = United States, South.....	17,739	41.1%
4 = United States, West.....	10,621	24.6%
5 = Europe.....	4,164	9.7%
6 = Asia/Pacific Islands.....	3,921	9.1%
7 = Other.....	2,183	5.1%
8 = Unknown/Missing.....	217	0.5%
	=====	
	43,113	

Description: After the end of data collection, REGION3 was identified as a significant predictor of the likelihood of response.

Variable: VSTRAT

Length: 3

Label: Variance Estimation Strata

Values: VSTRAT is a continuous variable with the following distribution:

Maximum 234

Median 104

Minimum 1

Description: A stratified random sampling design was used for the 1996 EOS survey. The sampling frame was stratified for each form by service, region, Paygrade groupings, and race/ethnicity groupings. Optimum allocation techniques were used to distribute the sample across the strata. Variance estimation requires at least two analysis records within each sampling stratum. Precision of the estimates improve as the average number of analysis records within the strata increases. Since nonresponse causes a decrease in the number of records, several strata were collapsed. Strata were combined based on the stratum variables and the response pattern within the strata. Thus weighting class strata (VSTRAT) were formed by collapsing the sampling strata to obtain a minimum sample size of 25 respondents. Sampling frame counts were calculated within the weighting class strata for analysis purposes.

See Appendix E for recommended uses of the variable during analysis.

Weighting and Analysis Variables

Weighting and analysis variables included in the DMDC Internal Use Analysis File are described in the subsequent pages. The variable information is displayed using the following format:

<i>Label:</i>	variable name
<i>Len:</i>	length or size of the variable
<i>Description:</i>	description of the variable
<i>Freqs:</i>	number of records containing a particular value or range of values
<i>Pct:</i>	percent distribution associated with the frequencies

The variable name (*Label*) is the name of the variable on the data set. The size of the variable (*Len*) includes the variable length and the type of variable, such as numeric or alphanumeric. Alphanumeric variables can be identified by an "A" before the variable length. The description of the variable (*Description*) includes information such as the label and values of the variable. Variable values are displayed (*Description*) in one of two ways depending on the type of variable. Frequency distributions are used for categorical variables. Ranges of values are used for continuous variables. The total number of records for each level of the variable (categorical) or within the valid range (continuous) is given in the *Freqs* column while the range is provided in the *Description* column. The percent distribution (*Pct*) is provided for the categorical variables.

Final Analysis Variables

See the Missing Data Compensation Procedures section and Appendix E for recommended uses of the variables during analysis and for details concerning the use of the following variables during the construction of analysis weights.

Label	Len	Description	Freqs	Pct
ANL_WT	8	Analysis Weight		
		0 = Nonrespondent Weight.....	33,641	43.8%
		Positive Range = 1.06 - 579.45.....	43,113	56.2%
			<u>76,754</u>	
ELIGFLGW	3	Indicator for Subject Eligibility		
		0 = Ineligible Subjects.....	3,258	7.5%
		1 = Eligible Subjects.....	39,977	92.5%
			<u>43,235</u>	
NVSTRAT	4	Frame Count Within Variance Stratum		
		Range = 26 - 85,127.....	76,754	100.0%
WGHT_FLG	3	Response Indicator		
		0 = Nonrespondent	33,641	43.8%
		1 = Respondent	43,113	56.2%
			<u>76,754</u>	
RSPADJWT	8	Response-adjusted Sampling Weight		
		0 = Nonrespondent Weight.....	33,641	43.8%
		Positive Range = 1.04 - 596.42.....	43,113	56.2%
			<u>76,754</u>	
VSTRAT	3	Variance Estimation Stratum		
		Range = 1 - 234.....	76,754	100.0%

Intermediate Weighting Variables

See the Missing Data Compensation Procedures section for details concerning the use of the following variables during the construction of analysis weights.

Label	Len	Description	Freqs	Pct
DENBLK2	3	Black Density Category (4)		
		1 = Low (Enlisted, 2.4%-22.3%).....	33,351	43.5%

SAS Code Used for Constructing Variables

This section gives the SAS coded used for constructing variables on the files. Data from the ADMF and the RCCPDS were used in addition to data from the sample file. This appendix gives SAS code the following variables:

DENBLK2
DENHSP2
DENMNR2
EDLEVEL
ELIGFLGW
INELCODE
MISRELQS
MISSCNT
NRSPCODE
REGION3
RMARITAL
WGHT_FLG
SEG1A-SEG182

The following section of SAS code was used to create the indicator variables to distinguish study respondents from the study nonrespondents (WGHT_FLG) and eligible respondents from ineligible respondents (ELIGFLGW). First, nonrespondents were identified from those questionnaires which were returned; those individuals who did not answer at least one item from questions 29, 30, or 31 were classified as nonrespondents. The number of missing items in questions 29, 30, and 31 was calculated (MISCTQ29, MISCTQ30, and MISCTQ31, respectively). If the sum of these three numbers (MISSCNT) equaled 57, then the study subject was classified as a nonrespondent. After identifying those subjects who did not answer the relevant questions from the questionnaires (MISRELQS), the response status code was created (RESPSTAT) using some additional variables from the survey control system:

BLKREAS	Reason survey returned blank
DISPO	Disposition variable
EF071096	July 10, 1996 eligibility code
EF101796	October 17, 1996 eligibility code
EFWAVE2	Wave 2 eligibility code
REFUSE	Refusal indicator
SCSINEL	Flagged ineligible in survey control system

From the response status code, the study respondent indicator (WGHT_FLG) and the eligibility indicator (ELIGFLGW) were created.

/*****
 The following section of SAS code was used to create the ineligibility status code variable for the ineligible study respondents (INELCODE). The variable was created using the response indicator variable (WGHT_FLG) and the following survey control system variables:

BLKREAS	Reason survey returned blank
EF071096	July 10, 1996 eligibility code
EF101796	October 17, 1996 eligibility code
EFWAVE2	Wave 2 eligibility code
SCSINEL	Flagged ineligible in survey control system

*****/

```

PROC FORMAT;
  VALUE inelcode
    0 = "Study Nonrespondents"
    1 = "Ineligible Based On Military Records"
    2 = "Self-Report Ineligible"
    3 = "Eligible";
  
```

```

RUN;
  
```

```

IF EFWAVE2=0 or EF071096=0 or EF101796=0 THEN INELCODE=1;
ELSE IF BLKREAS in (1,4,5,6,10) THEN INELCODE=2;
ELSE IF 1<=SCSINEL<=3 or SCSINEL=5 THEN INELCODE=2;
ELSE IF WGHT_FLG=1 THEN INELCODE=3;
ELSE IF WGHT_FLG=0 THEN INELCODE=0;
  
```

The following section of SAS code was used to create the nonrespondent status code variable for the study nonrespondents (NRSPCODE). The variable was created using the response indicator variable (WGHT_FLG), the response status code (RESPSTAT), and an indicator for why the questionnaire was returned blank (BLKREAS).

/*****
The following section of SAS code was used to create variables to categorize study subjects based on the percent
Black (DENBLK2), percent Hispanic (DENHSP2), and percent minority (DENMNR2) in their occupation group.
Subjects were first categorized as either officers or enlisted personnel (ENLOFF). The occupation group
(OCCGROUP) was a recode of the DoD Duty Occupation Code (DDOC) obtained from positions 7-9 of the ADMF
and the RCCPDS; this variable reflects the occupation in which the Service member was actually working . This
computer code was provided by DMDC.

```

The following section of SAS code was used to create variables to identify the regions of the US or the world. First, the subject's location (MEMLOC) was categorized into inside and outside the US (CREGION). Using the subject's location of duty assignment (DUTYLOC) along with the previously mentioned variables, a world location variable was created (CNTYST). This location variable was collapsed into 4 categories (REGION). A second region variable was created for those subjects residing in the US (CENDIST). An overall location variable was created by combining the information in the variables CENDIST and REGION (REGION3). A significant portion of the code was provided by DMDC.

```

This section of SAS code creates the segments used in the nonresponse weight adjustments. These segments take the value 0 or 1. The segments are created from values of the following variables:

CRACE	Race/ethnicity variable used for sampling
CSERVICE	Branch of the service variable used for sampling
DENBLK2	Recode of Black density in the sampled person's occupation group, created by earlier code in this section
DENHSP2	Recode of Hispanic density in the sampled person's occupation group, created by earlier code in this section
DENMNR2	Recode of minority density in the sampled person's occupation group, created by earlier code in this section
DPLOYIND	Deployment indicator, from the EOS Sample File position 145
EDLEVEL	Level of education, created by earlier code in this section
GENDER	Gender, with unknowns coded as Males
PAY	Individual levels of paygrade, from positions 14 and 15 of the ADMF and positions 15 and 16 of the RCCPDS
REGION3	Region of the US or world, created by earlier code in this section
RMARITAL	Marital status, with unknowns coded as "Single"

Appendix G

Glossary

Words in the glossary have been cross-referenced. If a word used in a definition has its own entry in the glossary the word appears in italics.

ADMF: Active Duty Master File

AGR/TAR: Members of the National Guard and Reserve currently on active-duty.

Analysis Weight: A *sampling weight* that has been modified to compensate for missing data or for other reasons.

Bias: The difference between the *expected value* of an estimate of a *parameter* and the value of the *parameter* itself.

Coefficient of Variation: The ratio of the *standard error* of a *parameter* estimate to the value of the *parameter*.

Confidence Interval: The *random interval* expected to contain a *parameter* value with a specified probability. In the context of repeated sampling, the specified probability is the proportion of intervals computed for all possible samples that contain the *parameter* value.

Confidence Interval Half-Width: Computed as one-half the width of the confidence interval. 95% confidence intervals are used in this report, and the half-width is computed as 1.96 times the standard error of the estimate.

Criterion Variable: Also called *dependent variable*.

Dependent Variable: In a regression equation, the random variable y is a function of other variables x_1, x_2, \dots, x_p . For example, $y=f(x_1, x_2, \dots, x_p) + e$, where the function f might be a linear equation, logistic equation, or other function. y is called the dependent variable and x_1, x_2, \dots, x_p are the *independent* variables. The “ e ” is a random error term.

Design Effect: The ratio of the variance of a *parameter* estimate obtained using a specified sampling design to the variance that would be obtained using a simple random sampling design with the same number of observations. Components of the design effect might include a stratification effect, clustering effect, *unequal weighting effect*, and finite population effect.

Dimensions of Stratification: Defined by the variables used in constructing strata.

DMDC: Defense Manpower Data Center.

Domain: Any subpopulation defined within the *inferential population*.

EOS: Equal Opportunity Survey.

Estimation Procedures: The form of the calculations used to compute sample estimates of population *parameters* and their associated variance-covariance structure. In general, the appropriate estimation procedures are derived from the probability structure used to obtain the observations.

Equal Opportunity Survey: The survey undertaken in 1996 to assess racial/ethnic issues in the active-duty military force.

Expected Value: The mean of a *random variable* or function of random variables.

Explanatory Variable: Also called *independent variable*.

Finite Population Correction Factor: The factor $1 - \frac{n_h}{N_h}$ is the proportion of stratum h that is not included in the sample. It results from sampling from a finite population, and multiplies the variance obtained using a random sample of size n_h from an infinite population. This factor reduces the estimated variance.

FPC: *Finite population correction factor*

Inferential Population: The totality of units about which inferences are to be drawn or conclusions reached. Often referred to as the target population.

Independent Variable: See *dependent variable*.

Item Nonresponse: Occurs whenever only partial information is secured for a *unit of observation*.

Key Domain: A subpopulation defined within the *inferential population* identified for use in determining the *sample size* and allocation.

Levels of Stratification: Defined by the values of the variables used to construct the strata.

Linear Statistic: A *statistic* computed as the sum and/or difference of *random variables*.

Mean Square Error: Squares of the average of the deviation of each estimate from the true value, averaged over all possible samples. It is distinguished from the variance in that the variance

is measured by taking deviations from the expected value of the estimates. The mean square error is also equal to $\text{Variance} + \text{Bias}^2$.

Missing Data Compensation Procedures: Modifications made to the *estimation procedure* to reduce or eliminate biases arising in association with *noncoverage* and/or *undercoverage*.

Noncoverage: Any failure to assign a positive *selection probability* to every unit in the *inferential population*.

Nonlinear Statistic: A *statistic* computed as the product or quotient of *random variables*. In matrix algebra, the concept of a quotient is replaced by the concept of a product formed with the inverse of a matrix.

Nonresponse: Occurs whenever one or more of the observation or response variable values required to compute a *parameter* estimate is missing or unknown.

Number of Observations: For this survey, refers to the number of persons eligible to participate in the survey who returned a questionnaire with key items completed.

Parameter: A constant expressing a defined property of a population or distribution, such as its mean or variance.

Population Variance: The average over all of the units in the population of the squared differences between the values of an observation or response variable and its mean.

Precision Requirements: The maximum values of the *sampling variances* to be associated with the sample estimates of specified *parameters*.

Poststratification: A partition, in the mathematical sense, of the population constructed using response variable values obtained for a sample. Each unit in the population belongs to but one post-stratum, and the set of all post-strata includes all individuals in the population.

Poststratification Adjustment: A modification made to the *analysis weights* to force the sample estimates of selected parameters to equal specified or known values.

Random Interval: An interval having a *random variable* as at least one of its end points

Random Variable: A function whose domain is a *sample space* and whose range is a set of real numbers.

RCCPDS: Reserve Components Common Personnel Data System.

Respondents: Individuals who returned a questionnaire with usable responses to questions about uninvited and unwanted racial behaviors (questions 29, 30, and 31).

Respondent Burden: The effort, usually time, required by an individual to fully respond to a survey.

Response Propensity Weight Adjustment: The inverse of the predicted probability of nonresponse. The predicted probability is computed from a logistic regression model where the independent variable is a 0-1 response indicator.

Response Rate: Defined as
$$\frac{\text{eligible respondents} + \text{known ineligible}}{\text{total sample}}$$

SAFS: Status of the Armed Forces Surveys.

Sample Size: The number of *sampling units* selected into the sample. Note that the sample size is not necessarily equivalent to the number of observations. The number of observations obtained in a given sample can be less than, equal to, or greater than the sample size depending on the *sampling design* and *response rate*.

Sample Space: A set associated with a real or conceptual experimental or sampling design such that each element of the set denotes an outcome of an implementation of the design and any implementation of the design produces an outcome that corresponds to one and only one element of the set.

Sampling Design: The probability structure used to obtain a collection of observations.

Sampling Error: The difference between a *parameter* value as determined from a sample and the value as determined by taking a complete count or census using the same methods of measurement.

Sampling Frame: A finite set of listing units with the information needed to identify, distinguish, and allow access to the units comprising the *inferential population* and with the auxiliary information needed for implementing the *sampling design*.

Sampling Units: The units to which the *selection probabilities* or *selection frequencies* are assigned.

Sampling Weight: The inverse of the expected *selection frequency*.

Sampling Variance: The average over all possible samples of the squares of the *sampling errors*.

Selection Frequency: The *selection probability* multiplied by the *sample size*.

Selection Probability: The probability with which a *sampling unit* is selected into the sample.

Standard Error: The square root of the *sampling variance*.

Statistic: A function of the observations obtained in a sample.

Stratification: A partitioning, in the mathematical sense, of the *inferential population* used to control the distribution of the sample. Each unit in the population belongs to but one stratum, and the set of all strata includes all individuals in the population.

Unbiased: The difference between the *expected value* of an estimate of a *parameter* and the value of the *parameter* itself is zero.

Undercoverage: Any failure to obtain information for all of the *units of observation* in a selected sample.

Unequal Weighting Effects: The effect on the *sampling variance* of unequal weighting of the observations. The effect is in the direction of increasing the sampling variances relative to equal weights unless the unequal weights are proportional to the values of the observation variables.

Unit Nonresponse: Occurs when no information is secured for a *unit of observation*.

Unit of Observation: The units on which observations are made or from which measurements or responses are obtained.

Unit Response Propensity: A sampled member's probability of responding to the survey.

Variable Survey Cost: That part of the total cost of a survey that depends on the sample size and allocation. Variable survey costs are contrasted with fixed survey costs, which remain constant regardless of the sample size.

Weighting Class: A grouping together of nonrespondents and *respondents* thought to have the same average response variable values.

Weighting Class Adjustments: The ratio of the sum of the *sampling weights* over all of the units in a defined *weighting class* divided by the sum of the sampling weights over all *respondents* in the same class.

Without Replacement: Once selected, a sampling unit is not at risk of being selected again in the same sample.

13. ABSTRACT (Maximum 200 words) This report describes the sampling design, sample selection, estimation procedures, and the missing data compensation procedures used for the Armed Forces 1996 Equal Opportunity Survey (EOS). The population of inferential interest for the EOS consisted of the worldwide distribution of active-duty Army, Navy, Marine Corps, Air Force, and Coast Guard members (including Reservists on active duty) below the rank of admiral or general, with at least six months of active-duty service. The main purposes of the survey were to provide survey data on types, frequency, and effects of racial/ethnic harassment and discrimination experienced by active-duty military; context, location, and circumstances under which the experiences occur; racial climate within the larger organizational climate; characteristics of the complaint process; and effectiveness of current policies/training designed to prevent, reduce, and eliminate racial/ethnic harassment and discrimination. Data collection was by mail starting August 1996 to a stratified random sample of 76,754 service members. Usable surveys were completed by 39,855. After making adjustments for eligibility and differential sampling rates across the various subgroups, the response rate was 52.7%. Survey development, administration, datasets, and results are reported elsewhere.

GENERAL INSTRUCTIONS FOR COMPLETING SF 298

The Report Documentation Page (RDP) is used in announcing and cataloging reports. It is important that this information be consistent with the rest of the report, particularly the cover and title page. Instructions for filing in each block of the form follow. It is important to ***stay within the lines*** to meet ***optical scanning requirements***.

Block 1. Agency Use Only/Leave blank.

Block 2. Report Date. Full publication date including day, month, and year, if available (e.g. 1 Jan 88). Must cite at least the year.

Block 3. Type of Report and Dates Covered. State whether report is interim, final, etc. If applicable, enter inclusive report dates (e.g. 10 Jun 87 - 30 Jun 88).

Block 4. Title and Subtitle. A title is taken from the part of the report that provides the most meaningful and complete information. When a report is prepared in more than one volume, repeat the primary title, add volume number, and include subtitle for the specific volume. On classified documents enter the title classification in parentheses.

Block 5. Funding Numbers. To include contract and grant numbers; may include program element number(s), project number(s), task number(s), and work unit number(s). Use the following labels:

C - Contract	PR - Project
G - Grant	TA - Task
PE - Program Element	WU - Work Unit
	Accession No.

Block 6. Author(s). Name(s) of person(s) responsible for writing the report, performing the research, or credited with the content of the report. If editor or compiler, this should follow the name.

Block 7. Performing Organization Name(s) and Address(es). Self-explanatory.

Block 8. Performing Organization Report Number. Enter the unique alphanumeric report number(s) assigned by the organization performing the report.

Block 9. Sponsoring/Monitoring Agency Name(s) and Address(es). Self-explanatory.

Block 10. Sponsoring/Monitoring Agency Report Number. (If known)

Block 11. Supplementary Notes. Enter information not included elsewhere such as: Prepared in cooperation with...; Trans. of...; To be published in... When a report is revised, include a statement whether the new report supersedes or supplements the older report.

Block 12a. Distribution/Availability Statement.

Denotes public availability or limitations. Cite any availability to the public. Enter additional limitations or special markings in all capitals (e.g. NOFORN, REL, ITAR).

DOD - See DoDD 5230.24, "Distribution Statements on Technical Documents."

DOE - See authorities.

NASA - See Handbook NHB 2200.2.

NTIS - Leave blank.

Block 12b. Distribution Code

DOD - Leave blank

DOE - Enter DOE distribution categories from the Standard Distribution for Unclassified Scientific and Technical Reports.

NASA - Leave blank.

NTIS - Leave blank.

Block 13. Abstract. Include a brief (Maximum 200 words) factual summary of the most significant information contained in the report.

Block 14. Subject Terms. Keywords or phrases identifying major subjects in the report.

Block 15. Number of Pages. Enter the total number of pages.

Block 16. Price Code. Enter appropriate price code (NTIS only).

Block 17. - 19. Security Classification. Self-explanatory. Enter U.S. Security Classification in accordance with U.S. Security Regulations (i.e., UNCLASSIFIED). If form contains classified information, stamp classification on the top and bottom of the page.

Block 20. Limitation of Abstract. This block must be completed to assign a limitation to the abstract. Enter either UL (unlimited) or SAR (same as report). An entry in this block is necessary if the abstract is to be limited. If blank, the abstract is assumed to be unlimited.
